## Rebuttal Expert Report

### Asbestos Property Damage Claims

#### Preface

RJ Lee Group, Inc. (RJLG) was asked by W. R. Grace & Co. (Grace) to prepare a report summarizing the work of RJLG and others related to asbestos-containing surfacing materials in buildings and the potential for those materials to pose an unreasonable risk of harm to building occupants. RJLG submitted an Expert Report<sup>1</sup> on January 15, 2007. A list of Claimants' expert reports, also submitted on January 15, is included in Appendix A. This Rebuttal Report responds to assertions set forth in several of those reports.

#### Executive Summary

Claimants argue that the mere presence of asbestos-containing materials (ACM) in buildings represents a significant risk to building occupants and maintenance workers. Their reports and testing do not, however, provide evidence of exposures related to the presence or disturbance of ACM in buildings, including Grace products. In fact, the only airborne measurements cited demonstrate that, like those reported by other investigators (including RJLG), exposures to building maintenance workers are well below OSHA limits. Claimants' experts suggest, but provide no evidence, that the presence of in-place ACM, asbestos in dust, or debris from ACM contribute to exposures to building occupants. Review of their reports and photo documentation indicate that the only location in the buildings where suspect debris is observed is immediately beneath in-place materials. Claimants provide no independent studies demonstrating that the presence of ACM in buildings contributes to airborne exposures. Claimants' experts do not address the numerous studies and findings (including those of the EPA) that airborne levels in buildings with ACM are not different than outdoor levels.

Claimants' experts Ewing, Longo, Bennett and Millette provided a voluminous set of documents purporting to demonstrate that the presence of Grace fireproofing and acoustical plaster products represents an ongoing source of airborne asbestos fibers in buildings. Millette did experiments to demonstrate that the dust and debris immediately below fireproofing and acoustical plaster contained components (vermiculite, gypsum, and chrysotile) consistent with the in-place product components. Ewing and Bennett provided dust sampling results and photographic documentation of the presence of debris in proximity to in-place ACM. Millette simulated disturbance of debris from ACM and collected air samples during the simulation. However, the only data Millette provided are photographs of chrysotile structures. In fact, none of Claimants' experts provided appropriate airborne concentration data that could be used to compare with regulatory levels or estimate risk.

---

<sup>1</sup> RJ Lee Group, Inc., Expert Report For Asbestos Property Damage Claims Lack of Hazard Proceeding, prepared for W. R. Grace & Co., January 15, 2007.

*Rebuttal Expert Report*

There are critical scientific problems with each of these studies. Millette recognized that the surface debris contained particulate other than that associated with the ACM but failed to determine if environmental chrysotile (i.e., chrysotile from other sources in the environment) was associated with the debris. Millette also failed to acknowledge that the asbestos clusters and bundles found in his sweeping of the ACM debris in no way resemble airborne structures found in building air. In fact, the fibers in his simulation air samples were much larger than fibers in building air.

The Claimants' experts suggest that, given their evaluations, the mere presence of asbestos in dust raises the specter of potential exposure to occupants and building maintenance workers. However, they provide no meaningful evidence of airborne asbestos exposures.

For over 20 years RJLG has been evaluating airborne concentrations of asbestos in buildings alleged to contain fireproofing and other building products manufactured by Grace and other manufacturers. These studies and investigations into the significance of asbestos-containing surfacing materials in buildings by other researchers have produced an extensive body of scientific data that lead to the following conclusions:

- In-place asbestos-containing surfacing materials do not spontaneously release or shed respirable asbestos fibers, nor, under conditions of normal usage, result in elevated airborne asbestos levels in buildings.
- Airborne asbestos fiber levels produced during impacts of ordinary operations and maintenance activities on in-place asbestos-containing surfacing materials do not result in airborne exposures to maintenance or other workers above the OSHA excursion limit or above the current or past OSHA Permissible Exposure Limit (PEL).
- The disturbance of ACM materials, dust or debris in the normal course of building operations produces airborne asbestos levels only in the immediate vicinity of the disturbance, and even those localized airborne levels are generally well below the OSHA PEL.
- Surface concentration of asbestos structures, measured using indirect preparation methods, is not an indicator of past release of respirable fibers or a predictor of the potential for future releases.
- For equivalent work histories, the expected lifetime exposure (i.e., concentration, frequency and duration of exposure) associated with airborne asbestos levels in buildings is only a small fraction of the projected lifetime exposure contemplated by the OSHA PEL concentration of 0.1 f/cc on an 8-hour Time Weighted Average (TWA).

Claimants' experts have not produced any data that either refutes the extensive body of data or that would lead to a different conclusion.

I hold the opinions in this report to a reasonable degree of scientific certainty. In addition to the opinions set forth in this report, I may also rely on or comment on the publications,

*Rebuttal Expert Report*

opinions, data and materials produced in discovery or contained in reports of other experts designated by the claimants or Grace in this action, and I reserve the right to amend or supplement this report as necessary.

Richard J. Lee, Ph.D.  
President  
RJ Lee Group, Inc.

## 1.0 Asbestos in Surface Dusts

Claimants' expert reports (see list in Appendix A) purport to demonstrate that asbestos can be found in dust of buildings in which an asbestos-containing surfacing material (including spray-on fireproofing) exists. These reports assume that surface dust sampling is a scientifically reliable procedure, that sonication of the dust during sample preparation does not affect either particle size or count, and that any free fibers observed in surface dusts originated in the asbestos-containing surfacing materials directly above the surface dusts.

### 1.1 Claimant Expert Reports Previously Reviewed and Discussed

In its Expert Report dated November 14, 2006<sup>2</sup>, a copy of which is attached and incorporated herein, RJLG addressed in detail the issues in the expert report of William E. Longo (Longo) dated October 25, 2006<sup>3</sup> which was again submitted on January 15, 2007.

RJLG's Expert Reports dated January 19, 2006<sup>4</sup>, and October 17, 2005<sup>5</sup>, copies of which are attached and incorporated herein, addressed another Longo expert report dated December 8, 2005<sup>6</sup> and an expert report prepared by William M. Ewing (Ewing) dated December 7, 2005<sup>7</sup>.

The following is a summary of the significant problems with the positions taken by the Claimants' experts:

- Claimants' experts do not address the fact that air sampling is required to assess asbestos exposure and that air sampling has been the only recognized industrial hygiene method of assessing the risk of airborne asbestos exposure.
- Claimants' experts do not address the peer-reviewed scientific literature that contradicts their positions concerning the dust method. The scientific literature, including the dust method itself, speaks to the limitations of the dust method including the disruptive effects of sonication and the lack of any correlation between asbestos in surface dust and airborne exposure.

*Rebuttal Expert Report*

- Claimants' experts assume, without any supporting analyses, that the surface dusts that were sampled originated from the nearby asbestos-containing materials and thus ignore issues of fiber transport from other sources.
- Claimants' experts provide no support for the position that sonication does not affect the size or number of fibers. The Federal court has ruled on this matter and determined that the indirect preparation procedure is not a reliable procedure.<sup>8</sup>

## 1.2 Claimants' Expert Reports Not Previously Reviewed and Discussed

In January 2007, Ewing reported on his inspection of 100 Pine Street in San Francisco, CA<sup>9</sup>. Dust samples collected by Ewing from that building were analyzed by Longo<sup>10</sup>. Ewing also submitted a report concerning the Anderson Memorial Hospital<sup>11</sup>. The Ewing reports discuss buildings that were inspected at different times over the last fourteen years, beginning with Anderson Memorial Hospital in 1993<sup>11</sup> and extending to various Arizona buildings in 2005<sup>15</sup>. The purpose of these inspections was to determine whether dust and or debris reportedly originating from asbestos-containing surfacing materials (including spray-on fireproofing) in the building could be found on top of ceiling tiles, light fixtures, or other surfaces in the building. Ewing assumes that the asbestos in the surface dust represents a potential for resuspension that must be controlled or eliminated. No air sample data from these buildings are presented by Ewing to document possible worker or occupant exposure.<sup>12</sup> In Ewing's reports on the Pine Street Building<sup>10</sup> and the Anderson Memorial Hospital<sup>11</sup> no data are presented to substantiate the claim that asbestos was found in the surface dusts.

Claimants' expert, Martin R. Bennett<sup>13</sup> (Bennett) submitted a report on 22 buildings located in Arkansas, Texas, Arizona and Connecticut<sup>14</sup>. Bennett reports on the dust found in a number of buildings that he inspected between September 9, 2006 and January 3, 2007. He also reports on the condition of the various surfacing materials found in the buildings and assesses the potential for future damage in each building. However, no airborne fiber concentration data were presented by Bennett that could be used to determine compliance with OSHA regulations or for use in establishing a risk to building occupants or workers.

## 2.0 Claimants' Experts' Simulations

In addition to the reports of dust sample analyses, Claimants' experts conducted simulations<sup>15</sup> of work activities during which they collected air samples. OSHA has specific requirements for evaluating air sample data for exposure. However, the Claimants' experts did not follow OSHA's procedures in reporting their air sample results from these studies and thus those results cannot be compared to OSHA's PEL nor can they be used for risk analyses. These simulations were extensively discussed in RJLG's prior Expert Report<sup>1</sup> and are further discussed below.

### 2.1 Tucson Experiment

In his report, Longo presented air sample concentrations from filters collected during four experiments performed at the Tucson Convention Center.<sup>16</sup> Each experiment, lasting no more than four minutes, evaluated airborne fiber concentrations resulting from the dry removal of surface dusts using one of four different procedures. The filters were analyzed in general accordance with NIOSH 7400 (phase contrast microscopy, PCM) and AHERA<sup>17</sup> (40 CFR Part 763, Appendix A to subpart E, transmission electron microscopy, TEM).

Longo does not present airborne asbestos concentrations in any meaningful manner that can be compared to regulatory or health-based limits for exposure to asbestos. Regulatory (OSHA) limits for asbestos exposure are based on 30-minute and 8-hour time periods.<sup>18</sup> In order to compare Longo's reported results to OSHA limits (1 f/ml and 0.1 f/ml, respectively), RJLG calculated Longo's PCM concentrations as time-weighted averages. None of these results exceeded the OSHA limits. In fact, they were well within OSHA regulatory limits despite the fact that Longo used improper work practices.

Recommended practices for cleaning dust that may potentially contain asbestos fibers are provided by the National Institute of Building Sciences<sup>19</sup> which recommends that the dust be wiped using "damp or treated dusting materials" or using a HEPA vacuum. Longo used improper dry removal procedures.

Finally, Longo also reported airborne asbestos concentrations developed using the AHERA TEM method. OSHA does not recognize analytical data developed using the AHERA method.<sup>20</sup> Despite the use of an inappropriate method, RJLG evaluated Longo's fiber data derived from his AHERA TEM analysis. When Longo's TEM data<sup>21</sup> are restricted to fibers of a size that are visible in the PCM microscope (OSHA fibers), none of his air samples exceed OSHA regulatory levels.

<sup>21</sup> Longo's TEM data for three samples (7, 8 and 9) were not produced as part of Appendix A to Longo's report.

## 2.2 Claimants' Simulation Reports Not Previously Reviewed and Discussed

Ewing submitted an addendum to the Tuscon report dated January 11, 2007<sup>22</sup>. James R. Millette (Millette) submitted a report dated October 25, 2006<sup>23</sup>.

As set forth in RJLG's November 14, 2006 Rebuttal Expert Report,<sup>2</sup> Claimants' experts repeatedly misrepresented Dr. Lee's position with respect to alleged fiber release from Grace products. Claimants' experts continue to mischaracterize Dr. Lee's position here by suggesting that Dr. Lee has opined that the only fibers that are released from Grace products are fully encased in binder materials (the "corn dog" theory). This is not Dr. Lee's position. As discussed RJLG's January 15, 2007 Expert Report,<sup>1</sup> whenever the Grace surfacing products are disrupted, the fracturing occurs in the binder, resulting in the release of particles that are a mixture of asbestos, binder, and other fillers "with very few, if any, free asbestos fibers produced".

Millette purported to address this issue by conducting a simulation by walking on MK-3 debris particles and subsequently sweeping-up the debris. In this experiment, Millette did not report any airborne fiber concentrations, but did show photographs of bundles of fibers that became airborne during the tests. Millette failed to acknowledge these particles, because of their size, are non-respirable particles that are larger than any bundle reported in the dust data reviewed for this report and are larger than airborne asbestos fibers observed in building atmospheres<sup>24</sup>. These particles will not remain airborne due to their size.

Both Millette and Ewing, in their supplemental reports, discuss other simulations that were conducted more than 10 years ago<sup>25,26</sup>. Each of these reports fails to provide sufficient information to permit a comparison of the data with current (or past) OSHA occupational exposure levels. The time-weighted average (TWA) concentrations for the samples are not reported. In the cable pulling experiment, the air samples were analyzed using an indirect preparation procedure rendering the results meaningless as to airborne exposure.

### 3.0 Summary

The published literature shows that surface dust sampling and analysis for asbestos content is not scientifically reliable<sup>27</sup>. While dust samples may provide information on the presence or absence of asbestos in a sample, they do not provide information about the concentration of asbestos fibers in the air which is needed to assess exposure. The indirect sample preparation method has been unfavorably peer-reviewed and has been shown to have a built-in, uncontrolled bias and is inherently non-reproducible.

Building surface dusts contain materials that have been transported long distances prior to deposition. Where materials are locally damaged, the debris will fall and impact the surface because the particles are typically too large to be transported by the moving air. Free asbestos fibers are ubiquitous in our environment and are even found in surface dusts in buildings that never contained any asbestos-containing materials<sup>28</sup>. To find such fibers in surface dust is neither unusual nor surprising, but to conclude they originated only from nearby ACM materials ignores the laws of physics and is not supported by any scientific analyses.

The issues related to dust analyses have been discussed in depth in prior RJLG Expert Reports<sup>1,2,4,5</sup>. In summary, the presence of asbestos in surface dusts has not been shown to be related to airborne fiber exposures nor has the surface dust been related to risk analyses.

As stated previously, Claimants' experts do not address the fact that air sampling is required to assess asbestos exposure and that air sampling is the only recognized method of assessing the risk of airborne exposure. The Claimants' expert reports did not include the time-weighted concentrations for the reported air samples and did not evaluate the air sample data as directed by OSHA in order to determine whether the results were above or below OSHA's PEL. As reported, the Claimants' airborne fiber concentrations provide no scientifically meaningful basis to determine risk or the presence of a hazard. However, when RJLG evaluated the data from these simulations following OSHA's requirements, the airborne concentrations are shown to be well within OSHA's regulatory limits for occupational exposures.

## Rebuttal Expert Report

### 1.0 Preface

W. R. Grace & Co. (Grace) requested that RJ Lee Group, Inc. (RJLG) prepare an expert report related to dust sampling methodologies. RJLG submitted its initial Expert Report on October 17, 2005<sup>1</sup>, a copy of which is attached and incorporated herein. Two reports were submitted on behalf of asbestos property damage claimants: a report by Dr. William Longo dated December 8, 2005<sup>2</sup> and a report by Mr. William M. Ewing dated December 7, 2005<sup>3</sup>. RJLG submitted a Rebuttal Expert Report dated January 19, 2006<sup>4</sup>, a copy of which is attached and incorporated herein. This Rebuttal Report responds to the assertions set forth in the Expert Report of William E. Longo, Ph.D., Prepared on Behalf of the Property Damage Asbestos Claimants Represented by the Law Firm of Dies & Hile, LLP (the "Longo Report") dated October 25, 2006<sup>5</sup>.

### 2.0 Summary

The Longo Report purports to demonstrate that surface dust sampling is a scientifically reliable procedure, that sonication of the dust during sample preparation does not affect either particle size or count, and that any free fibers observed in surface dusts originated in the sprayed-on fireproofing directly above the surface dusts. There are significant problems with Longo's positions including:

- The Longo Report does not address the peer-reviewed scientific literature that contradicts his positions concerning the dust method. The scientific literature speaks to the limitations of the dust method including the disruptive effects of sonication.
- Longo assumes, without any supporting analyses, the surface dust that he sampled originated from the nearby asbestos-containing materials and ignores issues of fiber transport.
- The reported airborne fiber concentrations, even taken at face value, do not exceed, and are well below, regulatory limits for asbestos exposure.

- Longo provides no support for his position that sonication does not affect the size or number of fibers. Contrary to this position, Longo's own reported fiber sizes in samples prepared using direct and indirect preparation demonstrate the adverse and disruptive effects of sonication.
- The Longo Report suggests that the air fibers and dust fibers in the samples Longo analyzed are the same size and therefore the dust fibers can be used as an indicator of airborne asbestos exposure. However, RJLG's analysis of Longo's air and dust fibers show that the air and dust fibers are not the same size. Rather, the air and the dust fibers have statistically different size distributions thereby refuting Longo's claim that the asbestos in the dust can be used to estimate airborne asbestos concentrations.
- Longo repeatedly purports to set forth Dr. Lee's opinions but in doing so he grossly mischaracterizes Dr. Lee's stated positions.

### 3.0 Background

The Grace Monokote-3 (MK-3) and Zonolite acoustical plaster products are materials that meet the ASTM's definition of cementitious. The nature of these products is such that the asbestos was encapsulated and bound to the matrix. If mechanically disturbed or intruded upon, the system will fracture in such a manner as to release composite particles, not free, respirable fibers. These materials have been subjected to a variety of air erosion tests<sup>6,7,8</sup> that demonstrated, using then state-of-the-art methods, that they did not release asbestos fibers. In addition, RJLG has subjected one of these materials to extensive pulverization tests<sup>9</sup>, demonstrating that no significant airborne fiber levels were produced by the action.

Cementitious building materials do not spontaneously release fibers, delaminate or lose adhesion if they are correctly applied and if the building is properly maintained. Correctly applied and maintained cementitious fireproofing material will withstand degradation due to impact, bending, compression and air erosion. The materials of interest in this case are inert, nonreactive materials. They have been consolidated into a system that in and of itself will not degrade or deteriorate. Unless improperly applied or subjected to adverse environmental conditions, these materials will maintain their

integrity. These materials have been subjected to impact tests and no evidence of cracking, delamination or flaking was found.<sup>10</sup>

The Longo Report investigates a series of buildings that allegedly contain Grace asbestos-containing materials (ACM). The studies include experiments conducted in the Tucson Convention Center Music Hall, the Lancaster Keist Branch Library in Dallas, Texas, a series of buildings in Houston and Amarillo, Texas, and several building complexes in Arkansas. In all four experiments, a fine layer of dust and/or larger pieces of debris were found on surfaces directly beneath or in the vicinity of Grace's ACM products, including MK-3 fireproofing and Zonolite acoustical plaster. Longo assumes that the asbestos-containing dust is a result of Grace ACM products, and concludes that the asbestos in the dust is not encapsulated by matrix material and is in the size range that is respirable by building occupants or maintenance personnel.

#### 4.0 Sources of Surface Dust

Millette and Hays state that the composition of building dust can be a "combination of particles resulting from human (and pet) activities, general degradation of building materials, and a contribution from the outdoor dust that comes in by a variety of ways including the air system, through open windows, or carried in on shoes" and the "relative contribution of each source will vary according to geographic location, location within the building, and activities which occur in the building, including the type of air-conditioning and ventilation system."<sup>11</sup> There are a variety of sources that can contribute to outdoor dust that can then enter a building and deposit as surface dust throughout the building. Industrial emissions can contribute to outdoor dusts, including those from garbage dumps, chimneys, smoke stakes, stockpiles, and vehicle emissions. Outdoor dust can also be comprised of material from demolition, construction or abatement activities within the local vicinity of the building in question. The natural degradation of the building itself due to contact with the elements such as wind, heat, sunlight, rain, snow and hail may also produce constituents of outdoor dust. The natural weathering of rocks and minerals in the environment can create fine particles that may become airborne and thus become a component of outdoor dust. Finally, airborne dust may also contain a variety of organic material, including pollens, spores, and decaying vegetable materials<sup>11</sup>.

## 5.0 Summary of Longo's Building Studies

### 5.1 Tucson Experiment

Materials Analytical Services (MAS)<sup>12</sup> designed and conducted a study in the Tucson Convention Center (TCC) Music Hall where MAS asserts that Grace's MK-3 fireproofing was applied to structural steel members, I-beams and corrugated metal pan decking throughout the building. According to the Longo Report there was also fireproofing application on the concrete block walls, catwalk hand rail, HVAC equipment and ceiling hangers throughout the attic space. MAS accessed the fireproofing through the 5th floor attic located above the general seating area of the hall. The Longo Report states that the attic contains a variety of HVAC and lighting equipment. Building engineers reported that no significant renovation work or asbestos work had taken place in the building.

MAS inspected the horizontal surfaces below the sprayed decking and beams and discovered evidence of a layer of fine dust with sporadic areas of pea-size to fist-size chunks of debris. MAS assumed that the dust and debris were a result of the Grace's MK-3 fireproofing material. MAS did not collect any surface dust samples and they did not collect any samples of the fireproofing material. They did not correlate the observed surface dust with the actual fireproofing prior to dust re-entrainment and air sample collection. The only surface dust samples MAS used in their comparison were five samples they say were collected from the TCC Music Hall approximately one year prior to the experiments and a set of dust samples collected in a series of Arkansas buildings that allegedly contained Grace fireproofing materials.

### 5.2 Lancaster Keist Branch Library Experiment

In 1991, Mr. William M. Ewing (Ewing) performed a ceiling tile replacement study at the Lancaster Keist Branch Library in Dallas, Texas in which the asbestos-containing fireproofing was previously identified by a constituent analysis as a product 'equivalent' to Grace's MK-3. The study involved the replacement of twenty 1' x 1' ceiling tiles beneath the fireproofing. Dust and debris were observed on top of the ceiling tiles prior to removal and replacement. Longo performed no analyses to determine that the dust originated from the fireproofing above the tiles. Air samples were collected during the tile replacement and dust samples were collected following the tile replacement. The air samples were prepared and analyzed with a direct TEM method.

### 5.3 Texas Buildings Surface Dust Analysis

In September of 2006, MAS visited four buildings in Houston and Amarillo Texas to collect surface dust samples from areas in the vicinity of in-place Grace MK-3 fireproofing and Zonolite acoustical plaster. The dust samples were collected and analyzed in accordance with the ASTM D-5755 method. MAS stated that the direct preparation

---

<sup>12</sup> Materials Analytical Services (MAS) is Dr. Longo's firm.

method showed respirable-size asbestos structures as well as non-encapsulated asbestos structures.

#### 5.4 Arkansas Buildings

In September of 2006, MAS visited four building complexes in Arkansas in order to collect surface dust samples from areas in the vicinity of in-place Grace MK-3 fireproofing or acoustical plaster. The dust samples were collected and analyzed in accordance with the ASTM D-5755 method. In 16 out of 28 samples Longo reports asbestos concentrations greater than 1 million structures per cm<sup>2</sup>.

### 6.0 Problems with Longo's Building Studies

The source of the surface dust found in the buildings examined by Longo was never shown to be directly correlated to the ACM products present in the building. As described by Millette and Hays<sup>11</sup>, building dusts can be comprised of particles, including asbestos fibers, from the outdoor dust that come from a variety of sources. However, the bulk ACM products that Longo claims the surface dust originated from were never visually examined, documented or sampled and analyzed. In addition, the building environment, activities and history were not taken into consideration.

Ewing's report of December 2005 states that the "presence of dust and debris is usually an indication of damage or deterioration of ACM" and that the "visual assessment of the ACM is the primary assessment tool". Ewing reiterates the point by stating that "Surface sampling is not used alone. Most often it is a tool used in conjunction with visual assessment." The Longo Report provided no visual assessment or photographs detailing any potential damage or deterioration of the fireproofing or acoustic material. Longo collected samples without a detailed examination of the surroundings.

In addition, no samples were collected from the ACM products in order to correlate the dust and/or debris with the ACM product material. A variety of other factors can contribute to the composition of building dust as described above, including other ACM products in the building and outdoor dust that enters the building through the air and ventilation systems. Longo did not explore or mention the possibility of other ACM products in any of the buildings he sampled. In the Tucson experiment, it was noted that the attic space where the sampling occurred contained a variety of HVAC and lighting equipment. No dust samples were collected from the HVAC system or from the supply and return air ducts.

The history of renovation and asbestos abatement also needs to be considered when determining the source of dust and debris in buildings. Longo's report notes that, according to building engineers, the Tucson Convention Center Music Hall had never had renovation or asbestos abatement work performed in the building. However, there was no mention of previous construction, renovation or abatement activities for the remaining three test sites.

## 7.0 Asbestos in Buildings with No ACM Products

It is well documented that asbestos is present in the dust in buildings that do not contain ACM product material. The General Services Administration (GSA) building study, published in May 1988, was designed to evaluate indoor air quality in (1) buildings without ACM, (2) buildings with ACM in good condition and (3) buildings with significantly damaged ACM.<sup>13</sup> There was no appreciable difference between outdoor and indoor air levels in any of the building groups. Of note, however, was that the single highest airborne asbestos fiber concentration was observed in a building with no ACM surfacing material.

In 1991, RJLG analyzed dust samples collected from three buildings in Baltimore,<sup>14</sup> all of which were built following the EPA ban on asbestos products in 1989. All three of the buildings were found to contain chrysotile and amphibole asbestos fibers in the building dust.

In 1998, RJLG published another study involving samples of air and surface dust from homes in the Los Angeles area following the 1995 Northridge earthquake.<sup>15</sup> The test sites were divided into homes with (1) no ACM, (2) ACM present in good condition, and (3) damaged ACM. The study showed that there was no significant difference between asbestos levels in surface dusts in homes with ACM and homes without ACM. In addition, the presence of asbestos in the surface dust was found to be independent of the presence of asbestos in bulk samples collected from the residences. Similarly, the presence of airborne asbestos was found to be independent of the presence of asbestos in the corresponding surface dust.

In 1996, Ewing published a report on settled asbestos dust in buildings in the EIA Technical Journal<sup>16</sup>. He published the same results in 1999 in an ASTM Special Technical Publication<sup>17</sup>. Ewing reports asbestos in surface dust samples in buildings with no ACM surfacing material and outside buildings (i.e., roofs, facades, and windowsills) in a large city. Ewing states that the positive asbestos results "demonstrate that asbestos structures can be found on such surfaces". He notes that the buildings with no ACM surfacing materials did contain other sources of asbestos such as floor tile, pipe/boiler insulation, drywall joint compound or asbestos board. He also notes that the source of asbestos fibers

from outside of the buildings may be due to fiber release from natural sources during groundbreaking or excavation projects.

Asbestos is ubiquitous in the environment. Finding asbestos in surface dusts in any building or outside of any building is not unique. Finding free asbestos fibers in surface dusts is not unusual or unexpected.

## 8.0 Longo Air Data Do Not Exceed Regulatory Limits

It is undisputed that asbestos health effects are related to the inhalation of airborne asbestos fibers<sup>18,19</sup> not to the presence of asbestos in surface dusts. Health effects are most closely related to long thin fibers<sup>19</sup>. Therefore, when analyzing asbestos fibers it is important to maintain the fibers in the condition in which they were collected without modification. While dust samples may provide information on the presence or absence of asbestos in the dust, they do not offer information needed for risk analysis (the concentration of fibers in the air)<sup>20</sup>. The ASTM dust method<sup>21</sup> upon which Longo relies recognizes this limitation, stating (Section 5.1.2) that "no relationship has been established between asbestos-containing dust as measured by this test method and potential human exposure to airborne asbestos."

Longo, however, attempts to make the very correlation that the method itself says is not possible by comparing the results of dust samples to the results of air samples. That attempt is scientifically flawed. Longo is not able to make a direct comparison of the fibers in the dust to the fibers in the air because he altered the dust fibers by sonication utilized during the indirect preparation of the samples. Additionally, Longo fails to acknowledge the body of peer-reviewed scientific literature which addresses the disruptive effects of sonication and the fact that there is no correlation between the asbestos fibers found in the dust and any asbestos fibers in the air.

In his report, Longo presented air sample concentrations from filters collected during four experiments performed at the Tucson Convention Center.<sup>22</sup> Each experiment, lasting no more than four minutes, evaluated airborne fiber concentrations resulting from the dry removal of surface dusts using one of four different procedures. The filters were analyzed

in general accordance with NIOSH 7400 (phase contrast microscopy, PCM) and AHERA (40 CFR Part 763, Appendix A to subpart E, transmission electron microscopy, TEM).

Longo does not present airborne asbestos concentrations in any meaningful manner that can be compared to regulatory or health-based limits for exposure to asbestos. Regulatory (OSHA) limits for asbestos exposure are based on 30-minute and 8-hour time periods.<sup>23</sup> In order to compare Longo's reported results to OSHA limits (1 f/ml and 0.1 f/ml, respectively), RJLG calculated Longo's PCM concentrations as time-weighted averages. Per the OSHA procedure, when there are two or more results per person per time period, these values are then averaged. As the results in Table 1 demonstrate, none of Longo's air samples exceed OSHA regulatory limits.

Table 1. Longo's Air Sample Results Compared to OSHA Limits

Test	Sample ID	Longo's Reported PCM Concentration	30-Minute TWA	8-Hour TWA
Rag Cleaning	1	< 0.45	< 0.15	< 0.01
	2	1.74		
	3	8.43		
	4	5.07	0.90	0.06
Hand Brushing	5	0.65	0.09	0.01
	6	0.64		
	7	6.62		
	8	2.55	0.61	0.04
Compressed Air	9	8.56	0.72	0.04
	10	5.82		
	11	5.89		
	12	7.96	0.69	0.04
Insulation Removal	13	1.92	0.52	0.03
	14	5.84		
	15	8.51		
	16	5.83	0.96	0.06

Moreover, when properly evaluated, Longo's air samples were well within OSHA regulatory limits despite the fact that Longo used improper work practices. Recommended practices for cleaning dust that may potentially contain asbestos fibers are provided by the National Institute of Building Sciences<sup>24</sup> which recommends that the dust

<sup>23</sup> OSHA, 29 CFR Part 1910.1001.

<sup>24</sup> National Institute of Building Sciences (1992). *Guidance Manual: Asbestos Operations & Maintenance Manual*, p. 264.

be wiped using “damp or treated dusting materials” or using a HEPA vacuum. Longo used improper dry removal procedures that effectively converted what should have been meaningful air sample results that would indicate airborne asbestos exposures into meaningless surface dust sample results that reveal nothing about exposures.

Finally, Longo also reported airborne asbestos concentrations developed using the AHERA TEM method. OSHA does not recognize analytical data developed using the AHERA method.<sup>25</sup> Despite the use of an inappropriate method, RJLG evaluated Longo’s fiber data derived from his AHERA TEM analysis. When Longo’s TEM data<sup>26</sup> are restricted to fibers of a size that are visible in the PCM microscope (OSHA fibers), none of his air samples exceed OSHA regulatory levels.

## 9.0 Longo Data Demonstrate the Effects of Sonication

Longo fails to discuss the published literature that accurately describes the adverse and disruptive effects of sonication on fiber counts. It is well documented that sonication increases fiber counts by liberating fibers from encapsulating matrices, breaking bundles of fibers into individual fibers, and fracturing the fibers into smaller, more numerous fibers thereby exaggerating the asbestos fiber count. Thus, Longo’s reported asbestos concentrations for dust samples do not accurately represent the asbestos in surface dust and debris. The very method<sup>21</sup> on which Longo relies states (Section 1.4.1) “The procedure outlined in this test method employs an indirect sample preparation technique. It is intended to disperse aggregated asbestos into fundamental fibrils, fiber bundles, clusters, or matrices . . . the procedure . . . may alter the physical form of the mineral fibers.”

In his report, Longo attempts to equate air and dust samples, suggesting that dust samples are surrogates for past airborne exposures and that the sizes of the fibers observed in the air samples are the same as the sizes observed in the dust samples.

While Longo claims that the size distribution of the asbestos fibers in the air is equal to the size distribution of the asbestos fibers in the dust, his fiber data demonstrate that he is wrong. His data demonstrate that the air samples have asbestos fibers much shorter than the asbestos fibers in the dust. These findings are consistent with the published literature discussed in RJ Lee Group’s October 2005 report.<sup>1</sup>

Figure 1 below shows the distribution of fiber lengths for air and dust that Longo reported for the Dallas samples.

---

<sup>25</sup> D. T. Crane (1998). Letter to J. Johnston, June 24, 1998.

<sup>26</sup> Longo’s TEM data for three samples (7, 8 and 9) were not produced as part of Appendix A to Longo’s report.

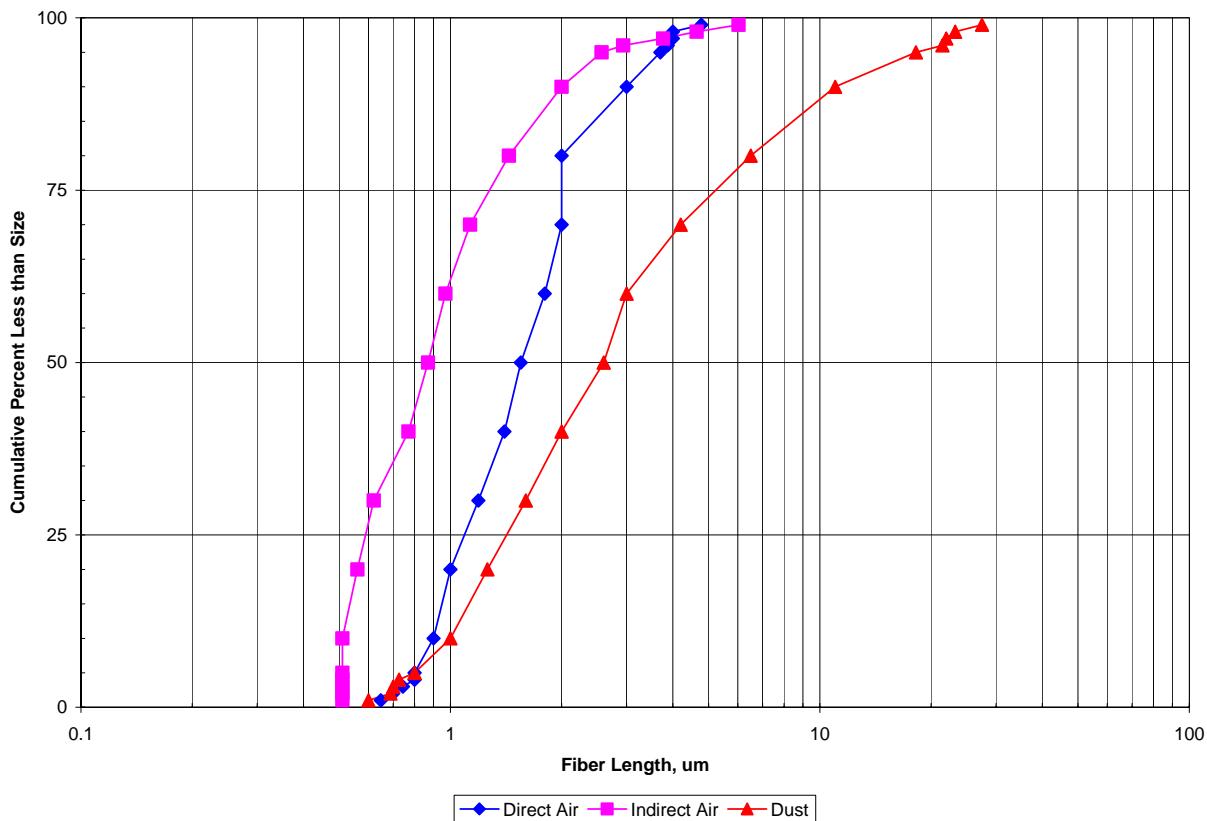

Figure 1. Distribution of Fiber Lengths Reported by Longo for Dallas Samples

Longo's Dallas air data shown in Figure 1 demonstrate the effects of sonication. In Figure 1, the air samples that were sonicated (Indirect Air, MVA0203) have fibers significantly shorter than the directly prepared air samples (Direct Air, M409022). Additionally, the data shows that the asbestos fibers in the dust are significantly longer than the fibers for either the directly or indirectly prepared air samples. These data demonstrate that the dust fibers are not the same as the air fibers, as Longo claims, and that dust samples cannot be used as a surrogate for air samples.

The fiber size data plotted from Longo's air and dust samples collected in Tucson is shown in Figure 2 below.

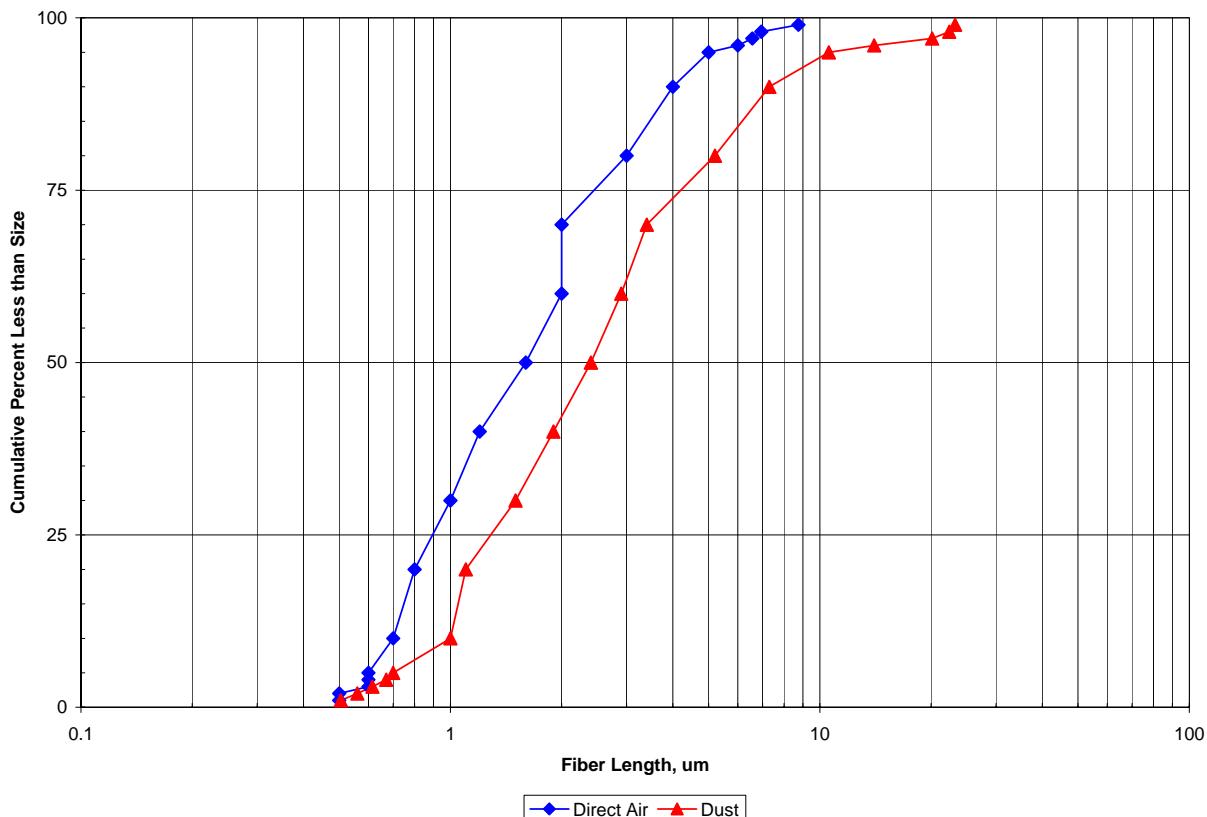

Figure 2. Distribution of Fiber Lengths Reported by Longo for Tucson Samples

As with the Dallas data, Longo's Tucson data show that the fibers in the dust are longer than the fibers in the air. Taken together, Longo's own data from Dallas and Tucson refute his contention that the air and dust fibers are the same size and that there are no effects due to sonication (indirect preparation).

The differences in air and dust fiber dimensions that are visually apparent in Figure 1 and Figure 2 are statistically significant. RJLG performed statistical evaluations on the fiber dimensions reported by Longo. In every case, these analyses showed that the size of the dust fibers is different than the size of the air fibers as observed in Figure 1 and Figure 2 and that these differences are statistically significant. Therefore, Longo's claim that the fibers in the air are the same size as the fibers in the dust is wrong. Longo's dust fibers are longer than the fibers in the air notwithstanding whether the air samples were prepared by direct or indirect preparation techniques. Thus, Longo's assertion that the dust can be used to document exposure in the air is not supported – and is in fact contradicted by – his own data.

## 10.0 Longo Mischaracterizes Lee's Position

In his report, Longo repeatedly purports to set forth Dr. Lee's opinions but in doing so he grossly mischaracterizes Dr. Lee's stated positions. Throughout his report (pages 2, 4, 5, 14, 15) Longo's reference to Lee's opinions as "all" or "none" is simply not correct.

Longo's report claims that Dr. Lee's position is that *any* release of asbestos-containing dust from in-place asbestos-containing surface treatment products in buildings is encapsulated and in *the particle size range that is not readily respirable* by building occupants or maintenance personnel." This has not been Dr. Lee's opinion. Rather, Dr. Lee has stated that "the constituents of the cementitious fireproofing materials and acoustical plasters at issue are stable and do not spontaneously degrade or shed individual fibers when physically or chemically attacked", October 2005 Expert Report, page 16.<sup>1</sup>

Longo claims Dr. Lee's opinion is that accumulated dust *does not contain free respirable asbestos structures* and that only large non-respirable asbestos-containing particles are found. Again, this misstates Dr. Lee's opinion. Dr. Lee has reported the presence of free respirable size asbestos structures in building dust including buildings which do not contain ACM<sup>14</sup>. It has been Dr. Lee's published position<sup>27</sup> and testimony that the number of free respirable fibers on a surface is thousands to hundreds of thousands times smaller than the numbers derived using indirect preparation methods. This is substantially different than a statement that no free fibers exist on a surface or that under no condition free fibers are released from fireproofing.

Longo also states that if Dr. Lee is correct that there are "no respirable size asbestos structures" in the surface dust then no respirable size asbestos particles should be found in the air. As pointed out above, Longo misquotes Dr. Lee's testimony and published work. Further, the issue is not whether free fibers exist on the surface, but whether surface dust measurements as practiced by Longo have any predictable value. Dr. Lee has published on this subject<sup>15</sup> and has repeatedly opined – consistent with statements in ASTM D5755 – that there is no relationship between the asbestos that is in the dust and the asbestos that may be in the air.

## 11.0 Summary

The published literature shows that surface dust sampling and analysis for asbestos content is not scientifically reliable<sup>28</sup>. While dust samples may provide information on the presence or absence of asbestos in the sample, they do not provide information about the concentration of asbestos fibers in the air which is needed to assess exposure. The indirect

<sup>27</sup> Lee, R. J., G. R. Dunmyre, "Direct Preparation: Innovative Sampling Technology, Applications for Other Indoor Air Contaminants", Presented at Settled Dust Sampling: Asbestos and Other Particulates, Georgia Tech Research Institute, Atlanta, GA, April 1992.

sample preparation method has been unfavorably peer reviewed and has been shown to have a built-in, uncontrolled bias and is inherently non-reproducible<sup>20</sup>.

Building surface dusts contain materials that have been transported long distances prior to deposition. Where materials are locally damaged, the debris will fall and impact the surface because the particles are typically too large to be transported by the moving air. Free asbestos fibers are ubiquitous in our environment and are even found in surface dusts in buildings that never contained any asbestos-containing materials. To find such fibers in surface dust is neither unusual nor surprising, but to conclude they originated only from nearby ACM materials ignores the laws of physics and is not supported by any scientific analyses.

Contrary to Longo's conclusions, his data document the adverse effects of sonication – when composite, multi-fiber particles are subjected to sonication, they are broken apart and release smaller particles and fibers; when asbestos fibers are subjected to sonication, they are fractured. These effects lead to smaller lengths and widths in the sonicated materials, thus materially changing the sizes and forms of asbestos as it exists in the building environment. The adverse effects of sonication are documented in Longo's data and are consistent with published literature.

## Rebuttal Expert Report

### 1.0 Introduction

Two expert reports were submitted by plaintiff's experts related to surface dust sampling. These reports (one by Dr. W. Longo and another by W. Ewing) purport to show that dust sampling has a long and established history, is a scientifically reliable method, and is useful in evaluating health risks. Of these three points, the issue of whether the method is scientifically reliable is the primary issue. Health risks can only be properly interpreted when the risk data are developed using reliable analytical procedures. The microvacuum method is flawed, in large part, because it modifies the sampled particles, altering the manner in which the particles were found on the surface and removing asbestos fibers from any matrix materials in which they were bound.

### 2.0 Scientific Reliability of the Method

The primary question to be answered is whether the method is scientifically reliable. Longo suggests the method has been favorably peer reviewed and has been tested to show an acceptable degree of reproducibility. Contrary to these opinions, the method has been unfavorably peer reviewed and has been shown to have a built-in, uncontrolled bias and is inherently non-reproducible.

The basic tenets of the microvacuum method have been reviewed by Lee<sup>1,2</sup>, Kauffer<sup>3</sup>, Sahle<sup>4</sup>, Chatfield, and others. Each of these reviews has shown the method to be an unreliable procedure for evaluating the number concentration of asbestos fibers in surface dusts. The reviews referenced by Longo (references 1, 3-7, and 9-11 on page 12 of Longo's report) were

conducted either by Longo's laboratory or by experts routinely retained by plaintiffs in property damage litigation.

The issues related to the microvacuum technique are illustrated by testing conducted on simulated building dusts. In each of these tests, the surface dust deposition was controlled so that a uniform layer of dust was generated for later sampling and analysis.

Crankshaw<sup>5</sup> created "dust" using calcium carbonate and chrysotile asbestos, mixed those materials in known concentrations, and distributed them in a dust chamber for later microvacuum sampling and analysis. Even with a uniform deposition of dust, Crankshaw's data show there is a 75% variability<sup>6</sup> in the asbestos structure counts.

Lee (reference 2) also tested a simulated building dust by mixing a reference clay/quartz material with approximately 1 kg of building dust collected from a building with asbestos-containing sprayed-on fireproofing. The mixed material was blown around a room in which various surfaces (ceiling tiles, wood, and carpet) had been placed. Samples collected from the ceiling tile and analyzed by a single laboratory show up to 57% variability of the asbestos structure counts.

Therefore, the data show that even with uniformly deposited "dusts", the sampling methodology employed by Claimants' experts yields substantial differences in analytical results (57 to 75% variability).

What components of the methodology produce such scientifically unacceptable results? The dust sampling techniques can be divided into sample collection, sample preparation, and sample analysis. Of these three parts, sample collection and sample preparation generate bias and non-reproducibility.

## 2.1 Sample Collection

A handheld sampling pump is used to vacuum the surface dust from a defined area into a cassette. As noted in the method, the sample area is "vacuumed until there is no visible dust or particulates matter remaining". However, the sampling technician is to "[a]void scraping or abrading the

---

<sup>5</sup> Crankshaw, O., Perkins, R. L., and Beard, M. E. (1996). "Quantitative Evaluation of the Relative Effectiveness of Various Methods for the Analysis of Asbestos in Settled Dust", *EIA Technical Journal*, 4, p. 6 - 12.

<sup>6</sup> Order-of-magnitude confidence intervals (intervals that range from 0 up to twice the reported value) on the average value of side-by-side samples require the sample variability to be no more than 11% for paired samples and no more than 40% when three samples are collected. For tighter (smaller) confidence intervals, lower levels of variability are required. ASTM is currently writing a guidance document for surface dusts (WK7719) where a 7% variability is used for example calculations.

surface being sampled". Particles larger than 1 mm are not to be collected. (Step 8.7 of D5755).

Microvacuuming is not performed consistently between different investigators, leading to differences in asbestos structure counts. In a sampling event conducted by Ewing and Van Orden at several Illinois universities, a particular window ledge was selected by Ewing for one sample collection event. The window ledge was on an inside window where Coca-Cola had been spilled (the can was on the window ledge). A section of the dried cola was completely sampled by Ewing, leaving no remaining cola or surface dust on the painted surface. On an area immediately adjacent, the sample collected under the direction of Van Orden could not remove the dried cola. The attached photograph, Figure 1, illustrates this difference in sample collection.

Two additional Figures show the differing degrees of particle collection by two sampling teams collecting from the same surface. In both photographs, the differences in sampling are visually apparent.

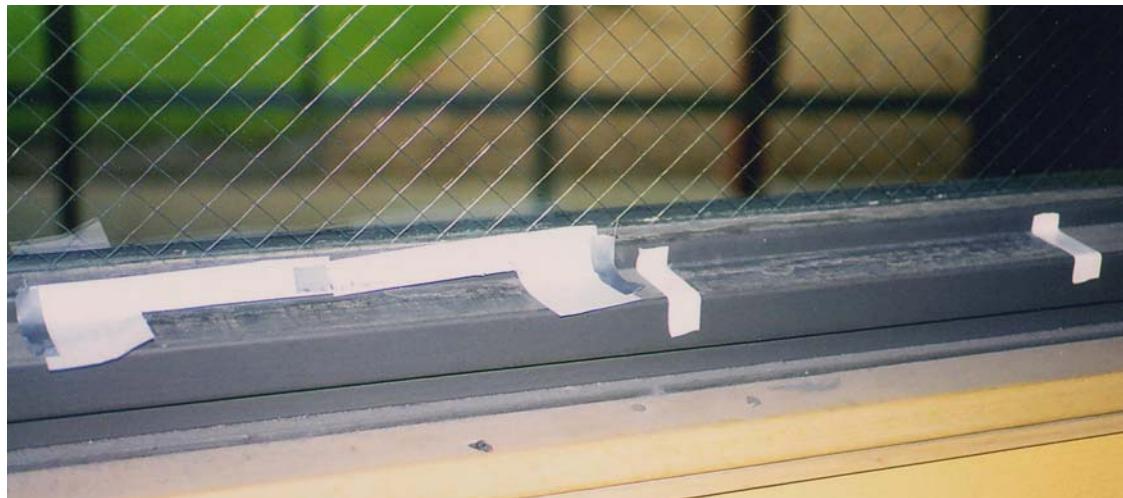

Figure 1. Photograph of the location of side-by-side microvacuum sampling collected by different personnel. The window ledge is on an interior wall where cola had been spilled and dried. The sample on the right scraped through the dried cola while the sample on the left scratched the surface but did not penetrate the dried cola.

Figure 2. Side-by-side samples collected on top of a projection screen by different personnel. Both samples scraped the surface, but the top sample cleaned the surface more thoroughly than the bottom sample.

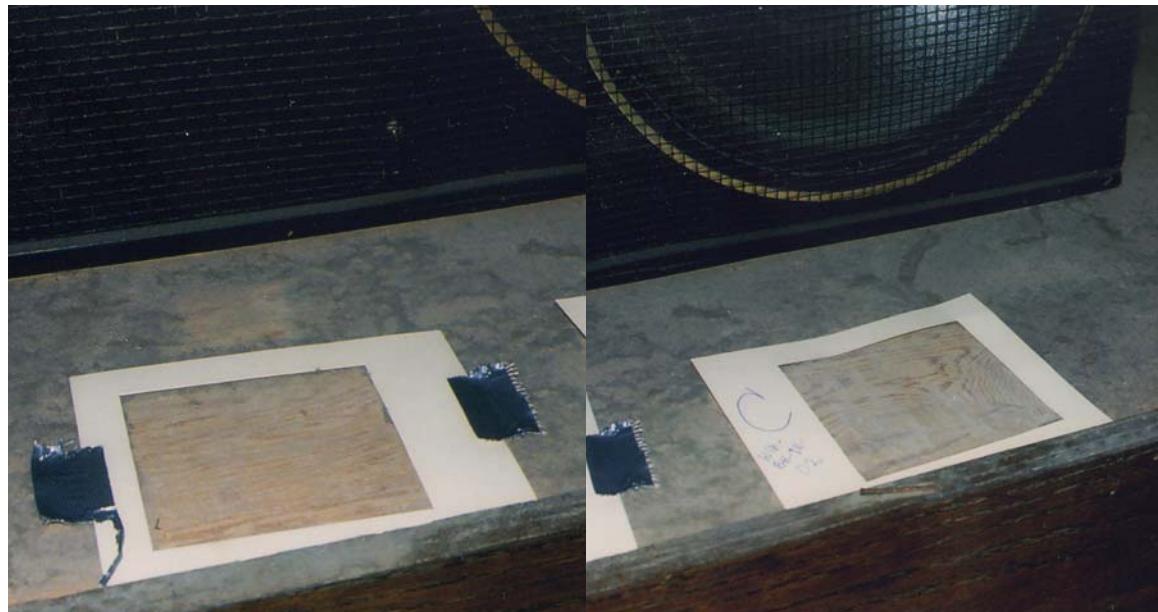

Figure 3. Side-by-side samples collected on a canopy located in a dining hall. The sample on the left removed more material than the sample on the right.

As evident in all three pictures, neither team collected the samples in accordance with the published method which states: "Avoid scraping or abrading the surface to be sampled."<sup>7</sup>

Thus, the process of collecting a microvacuum sample is not well defined nor is it applied in a consistent manner among individuals. These differences lead to variations in the reported asbestos structure counts.

## 2.2 Sample Preparation

The most widely discussed and criticized aspect of microvacuum sampling is the sample preparation portion of the method. Briefly, the preparation method encompasses the following steps: 1) rinse the dust out of the sampling cassette using an aqueous solution, 2) sonicate the suspended particles, 3) redeposit an aliquot of the sonicated particles on a clean filter, and 4) prepare the redeposit filter for analysis.

The most disruptive step in sample preparation is the sonication of the sample. During sonication, high frequency sound energy is transmitted through the liquid suspension causing cavitation. Cavitation is the formation of microbubbles that, when they collapse, cause shock waves to travel through the liquid at nearly the speed of sound. At the microscopic level, sonication is a highly disruptive force that, as noted in the ASTM D5755 method, "is intended to disperse aggregated asbestos into fundamental fibrils, fiber bundles, clusters, or matrices" and "may alter the physical form of the mineral fibers".

Sonication produces uncontrolled results. No U.S. promulgated analytical method for examining air filters in buildings or for evaluating worker risk to airborne asbestos uses an indirect preparation procedure. Similarly, because of this uncontrolled effect of sonication, the official air sample procedure for France forbids the use of sonication even though the method utilizes an indirect preparation procedure.<sup>8</sup>

The US EPA has published a study on the effect of the indirect preparation method.<sup>9</sup> As noted in the Executive Summary: "... measurements made by the indirect transfer method were 3.8 times to 1,700 times higher than measurements made by the direct transfer method." Also: "There is no single factor that can be applied to convert measurements made using an indirect transfer method to a value that is comparable with measurements made using a direct transfer method."

Dr. Longo contends the use of the indirect sample preparation procedure for the microvacuum method was "chosen to provide better precision and reproducibility than if the direct method were used." In fact, it was chosen because the microvacuum sampling method required that (at a minimum) enough dust be collected to darken the sample filter, thus precluding any direct preparation of the sample.<sup>10</sup> A filter will darken during sample

---

<sup>8</sup> Norme Française (1996). "Qualité de l'air: Détermination de la concentration en fibres d'amiante par microscopie électronique à transmission", NF X 43-050.

<sup>9</sup> EPA (1990). "Comparison of Airborne Asbestos Levels Determined by Transmission Electron Microscopy (TEM) Using Direct and Indirect Transfer Techniques", EPA 560/5-89-004, p. x.

<sup>10</sup> Clark, P. and Brackett, K. (1990). "Draft Test Method for Sampling And Analysis of Dust for Asbestos Structures by Transmission Electron Microscopy", US Environmental Protection Agency. As stated in

collection as more and more particles are collected. These particles will overlap, or lay upon each other, obscuring the white filter media. Because the particles are covering other particles, some collected asbestos fibers may also be obscured or covered. Thus, a direct preparation of the sample will not be able to detect these obscured fibers.

The microvacuum procedure permits the analysis of particles as large as 1 mm. The effect of processing such large particles was shown in a study in which a single large particle of chrysotile asbestos was submitted to various laboratories for analysis. (Lee reference 2) The results of these tests showed that a single large particle of chrysotile can generate anywhere from 20,000 to 22,000,000 s/cm<sup>2</sup> based on a sampling area of 100 cm<sup>2</sup>. Similarly, wide ranges of results were obtained when analyzing either a 0.5 mm particle of asbestos-containing fireproofing (1,000 to 630,000 s/cm<sup>2</sup>) or a 1 mm particle of the same asbestos-containing fireproofing (20,000 to 3,000,000 s/cm<sup>2</sup>). These large differences in results illustrate the uncontrolled nature of the sonication procedure.

The cause of these tremendous increases in the number of particles (from one particle to millions in the above examples) is the liberation of bound fibers from matrices and the comminution of the liberated fibers into shorter, more numerous fibers. The liberation aspect is proven by the testing of the 1 mm and 0.5 mm particles of an asbestos-containing fireproofing (noted above) as well as by videotapes<sup>11</sup> of the sonication of particles. Even one of the Claimants' expert microscopists in the Armstrong proceeding has acknowledged that the use of the sonication procedure increases the number of asbestos fibers.<sup>12</sup>

RJ Lee Group has shown how sonication changes the size of asbestos fibers. Lee showed that longer sonication times produced shorter fibers (Lee reference 1). In another test, air filters collected within a single building were randomly selected for analysis by either direct preparation or indirect preparation. After a large number of filters were prepared and analyzed, the data were collated and plotted as shown in Figure 4. In this data set, between 50 and 60% of the indirectly prepared fibers were shorter than 1  $\mu\text{m}$  while only 20% of the directly prepared fibers were shorter than 1  $\mu\text{m}$ . The indirect preparation procedure clearly reduced the length of the fibers.

"Exposure to Airborne Asbestos Associated with Simulated Cable Installation Above a Suspended Ceiling", American Industrial Hygiene Association Journal, 52, p. 479 - 484. "Moreover, sonication of ashed samples may disassociate bundles and clusters and disassemble matrices, thereby increasing the total number of structures counted."

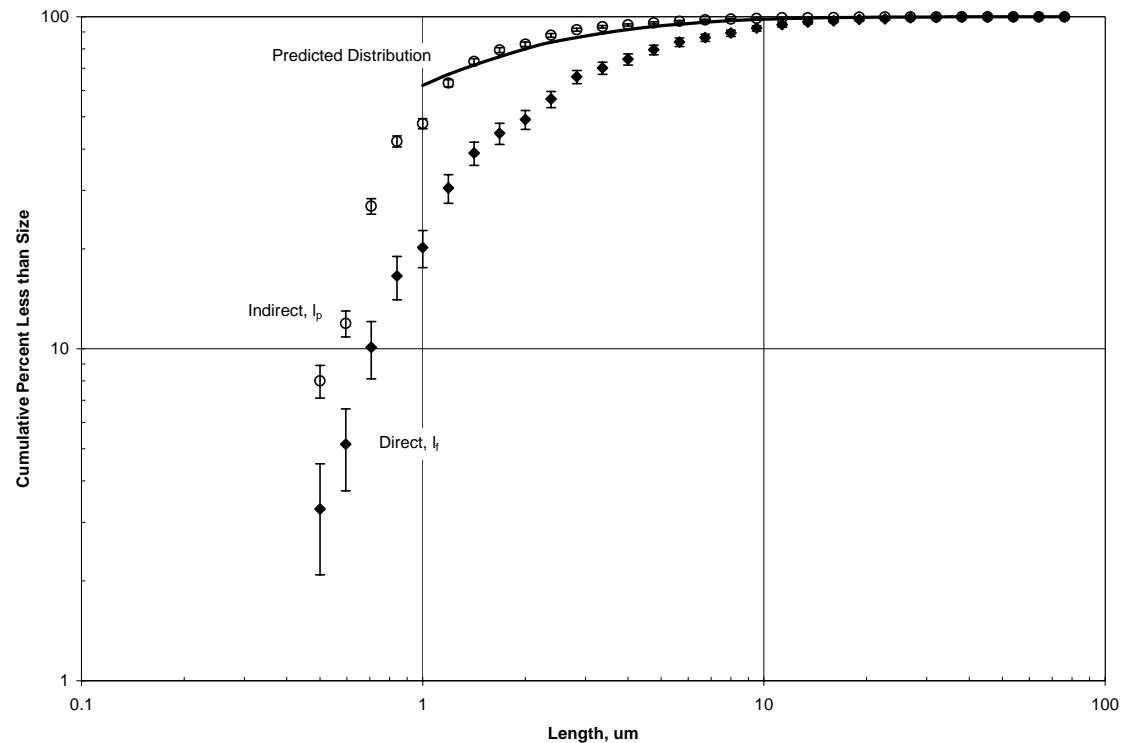

Figure 4. This graph shows the percentage of fibers that are shorter than a stated length. The Directly prepared fibers are solid circles; the indirectly prepared fibers are open circles. Error bars are plotted around each data point.

### 3.0 Method Reproducibility

As noted above, interlaboratory testing (sometimes referred to as “round robin” testing) of the method has shown the method to have a very large variability, enough to classify the method as non-reproducible for normal building dusts.

Dr. Longo simply asserts that round robin testing of the dust method shows it to be reproducible. Unfortunately, Dr. Longo failed to explain that all of the round robin tests conducted by MAS or on behalf of the ASTM committee are fundamentally flawed – none of the tests actually tested the entire microvacuum method. All of the round robin testing conducted by ASTM<sup>13</sup> was conducted on artificially prepared filters in which the test particles were subjected to sonication and deposition on filters, then sent to the participating laboratories. Therefore, the sonic disaggregation of the particles occurred prior to sending the particles to the laboratories, thus

<sup>13</sup> ASTM (2002). “Draft: ASTM Research Report No. xxxx for D5755”. The report only mentions five rounds of testing, not the six mentioned by Dr. Longo. M. Beard, the committee chairperson, confirmed in a telephone conversation 12/13/05, that he has no report for a sixth round, only for five rounds.

effectively removing this important step in the procedure from any round robin examination.

Dr. Longo uses his own sample data<sup>14</sup> to suggest the method has good reproducibility. Yet, in the two sets of data discussed in his publication, the first set used a calculation procedure not permitted by the ASTM method. In the second set of data, Dr. Longo calculated the variability of the microvacuum results from within each of 38 buildings. He then averaged the 38 calculated variabilities, erroneously assuming that the resulting average is a scientifically valid representation of both the variability due to microvacuum sampling and analysis as well as the variability due to the heterogeneous nature of building dusts. In fact, it represents neither.

Dr. Longo did not measure the variability due solely to microvacuuming and vastly underestimated the variability due to the heterogeneous nature of building dusts. As noted on page 3 of this report, even with supposedly uniform dust distribution, the dust methodology results in an unacceptably high 57 - 75% variability in the data. Even assuming the microvacuum sampling technique does not materially affect the reported data, the second data set (from Hatfield, et al, reference 14) significantly underestimates the variability within the building.

As shown in Figure 5, Dr. Longo understated the variability within a building by not collecting enough samples to produce scientifically valid and reliable data. Had he collected 11 samples in every building (as in Building 1 of his data), then the variability would have been much larger than the reported 97%, possibly approaching the 214% reported for Building 1.

---

<sup>14</sup> Hatfield, R., Krewer, J., and Longo, W. E. (2000). "A Study of the Reproducibility of the Micro-Vac Technique As A Tool for the Assessment of Surface Contamination in Buildings with Asbestos-Containing Materials", *Advances in Environmental Measurement Methods for Asbestos*, ASTM STP 1342, M. Beard and H. Rook, Eds., American Society for Testing and Materials, p. 301 - 312.

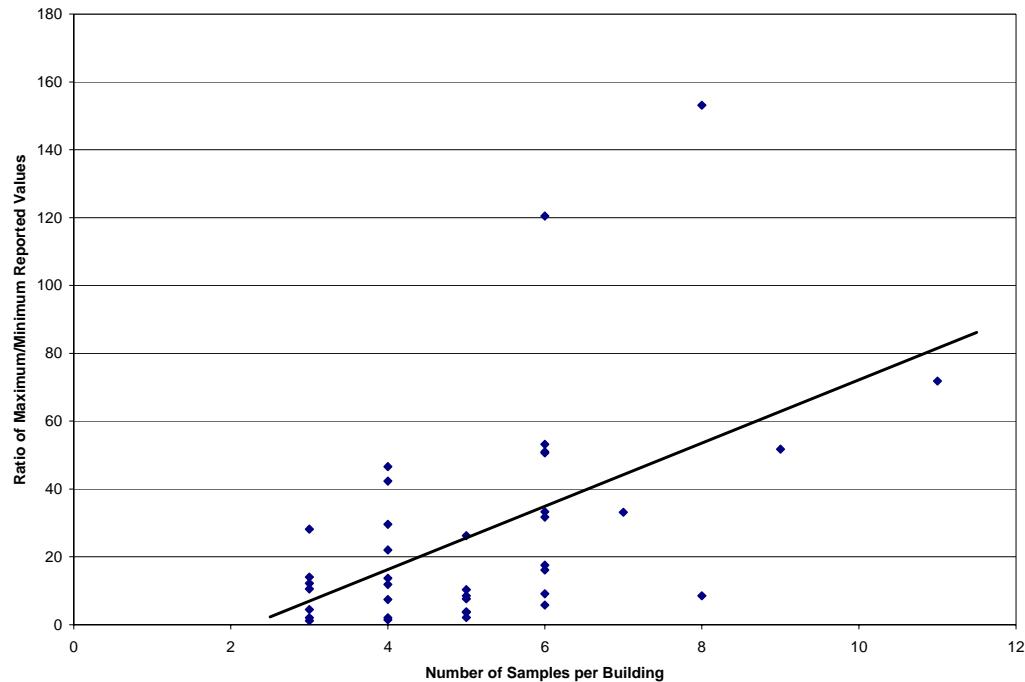

Figure 5. This graph shows that as more samples were collected and analyzed, the greater the range of data that were produced. The data were taken from Hatfield, et al.

Dr. Longo has also misinterpreted the results reported by Crankshaw, et al.<sup>15</sup> In that study, side-by-side samples in a basement indicated a nearly double increase in asbestos loading. Over the entire basement, the data were highly variable with one sample reporting 100 times as much asbestos as the first sample. In tests on lab-created samples, Crankshaw reported 20 times as much asbestos in one set of samples compared to another set, despite there being a 10-fold difference in deposited material.

Crankshaw also conducted a test where he deposited three times as much material in one area compared with another. In this test, the average reported result only increased by a factor of 30%. This increase in reported fiber loading occurred even though the amount of chrysotile deposited on the surface had increased by a factor of 300%. This further illustrates the unreliability of the test procedure.

<sup>15</sup> Crankshaw, O., Perkins, R., and Beard, M. E. (2000). "An Overview of Settled Dust Analytical Methods and Their Relative Effectiveness", *Advances in Environmental Measurement Methods for Asbestos*, ASTM STP 1342, M. Beard and H. Rook, Eds., American Society for Testing and Materials, p. 350 - 365.

#### 4.0 Method Development

Dr. Longo has suggested that the development of the ASTM microvacuum method consisted of nothing more than simple modifications of some non-technical issues. Dr. Longo further recalls that the "basic analytical procedure for preparing and analyzing surface dust samples did not change from the time it was first presented to the ASTM subcommittee in 1990 until its approval in 1995". Dr. Longo is incorrect in both his timeline and his recollection of the changes to the method. The following table documents some of the substantive revisions to the sample preparation portion of the method as it was developed by ASTM, beginning with the EPA draft method:

Item	EPA	6/7/89	12/5/89	1/23/91	10/1/91	11/12/91	4/9/93	1/28/94
Suspension	Ultrapure water	Particle free water and reagent alcohol						
pH adjustment	1% HCl	none	1% HCl	1% HCl	1% HCl	1% HCl	1% HCl or 10% Acetic acid	10% Acetic acid
Hand Shaking, s	none	30	30	"briefly"	"briefly"	"briefly"	"briefly"	2 – 3
Sonic bath, W	"Low power"	none	"Low Power"	"Low Power"	100 – 200	60 – 100	100	100
Sonication Time, min	10	none	10	3	3	3	3	3

As can be seen from the Table, substantial changes were made to the sample preparation portion of the method during its development. These are not simply "non-technical" changes. The change from Ultrapure water to a mixture of water and alcohol was made to reduce the dissolution of gypsum in the dust samples, as acknowledged by Dr. Longo in his report (page 21: using alcohol "has the effect of not dissolving any gypsum particles or mixtures"). Similarly, the change from hydrochloric acid to acetic acid was also made to reduce the dissolution of gypsum and carbonate minerals. The sonication of the suspension changed from none to 10 minutes to three minutes. All of these changes are technical and significant. In addition, because the effect of sonication was considered to be a critical element in the method, a calibration procedure for the ultrasonic bath was added following the balloting of the 1/28/94 edition.

## 5.0 Use of the Microvacuum Method

The legitimate use of the microvacuum method is to document the presence or absence of asbestos fibers in surface dusts. RJ Lee Group used the method in three large projects to document the extent of asbestos in surface dust in three office buildings (Delaware Trust, 130 Liberty Street, and 4 Albany Street buildings). That testing was done in connection with insurance claims to restore the buildings to their pre-event (a fire and the collapse of the World Trade Center) conditions. In each case, the microvacuum sampling was conducted to document that dust and debris had been spread throughout each building as a result of an event and was not present as a pre-event condition. In none of these buildings was the dust sampling performed to evaluate occupant or worker safety.

In contrast, Claimants' experts incorrectly purport to use the microvacuum method for dual objectives: 1) to document the extent of asbestos in surface dust in a building (and relative amounts of asbestos); or 2) to assess the "safety" of building occupants to possible exposure to asbestos-containing surface dusts.

The Claimants' experts unscientific use of the D5755 method to determine "safety" or levels of building "contamination" is seriously flawed due to the use of the indirect preparation procedure and disregards several explicit cautions set forth in the D5755 method. As noted in the method: "as with all indirect sample preparation techniques, the asbestos observed for quantification may not represent the physical form of the asbestos as sampled". (A similar statement was included in the EPA draft microvacuum method.) More specifically, the method states: "no relationship has been established between asbestos-containing dust as measured by this method and potential human exposure to airborne asbestos". The D5755 method also "does not describe procedures or techniques required to evaluate the safety or habitability of buildings with asbestos-containing materials, or compliance with federal, state, or local regulations". The uncontrolled increase in the number of fibers through liberation and comminution makes the interpretation of the asbestos structure counts impossible.

All current risk analyses procedures incorporate direct preparation of the air filters – there is no promulgated risk analysis procedure for the evaluation of asbestos in surface dusts. Even when the EPA developed a risk analysis procedure for soils and bulk materials<sup>16</sup>, the method was devised so that the analyzed samples were directly prepared air filters, not indirectly prepared filters.

---

<sup>16</sup> Berman, D. W. and Kolk, A. (2000). "Draft: Modified Elutriator Method for the Determination of Asbestos in Soils and Bulk Materials", Revision 1, May 23, 2000.

Because the indirect preparation procedure liberates (releases) fibers from any binding matrix, the asbestos structure counts are meaningless in terms of possible exposure.

Both Dr. Longo and Mr. Ewing suggest that the US Environmental Protection Agency (EPA) is using the microvacuum method to "make nearby buildings safe for occupancy" (Longo, page 10) at the World Trade Center. However, the COPC Committee<sup>17</sup> "elected against setting benchmarks for COPC [contaminants of potential concern] in settled dust", particularly for asbestos, because asbestos fibers "exert their toxicity primarily through the inhalation route of exposure". No health-based benchmarks were established for asbestos in surface dusts at the WTC site. Any benchmark created for the WTC site is strictly limited to the WTC site and is not applicable to other buildings.

Mr. Ewing suggests that RJ Lee Group agrees with the use of microvacuum test concentrations in the WTC vicinity by referring to a 2002 *USA Today* article. This reference is a misquote by the reporter who used a comment made by Dr. Lee about high airborne concentrations (reported by Chatfield<sup>18</sup>), not asbestos in dust, in a paragraph that discussed surface dusts.

Mr. Ewing cites to the EPA's use of dust sampling in Libby as condoning the use of D5755 by Claimants' experts. However, the EPA<sup>19</sup> in Libby "is not relying upon measured dust levels to decide if residential/commercial sources [of asbestos] must be addressed". After the EPA cleans a property, only visual inspection of the property and aggressive air sampling will be used to determine cleanliness. The EPA chose air sampling for clearance testing because asbestos in surface dust is not "directly correlated with risk estimates", while air concentrations directly correlate with risk estimates. (page 11)

## 5.1 Resuspension of Surface Dust

Both Ewing and Longo suggest that surface dust that contains asbestos may be resuspended in the air, thus causing an exposure to a building occupant or worker. They cite this action as one justification for surface dust

---

<sup>17</sup> COPC Committee (2003). "World Trade Center Indoor Environment Assessment: Selecting Contaminants of Potential Concern [COPC] and Setting Health-Based Benchmarks", contributors included the US EPA, OSHA, and ATSDR, p. 11.

<sup>18</sup> Chatfield, E. J. and Kominsky, J. R. (2001). "Summary Report: Characterization of Particulate Found in Apartments After Destruction of the World Trade Center".

sampling. Lee<sup>20</sup> has investigated airborne concentrations in buildings that were allegedly damaged by the 1995 Northridge earthquake and compared these with surface dust concentrations determined using the ASTM D5755 method. As can be seen in the following graph (Figure 6), there was no correlation between asbestos in air and surface dust.

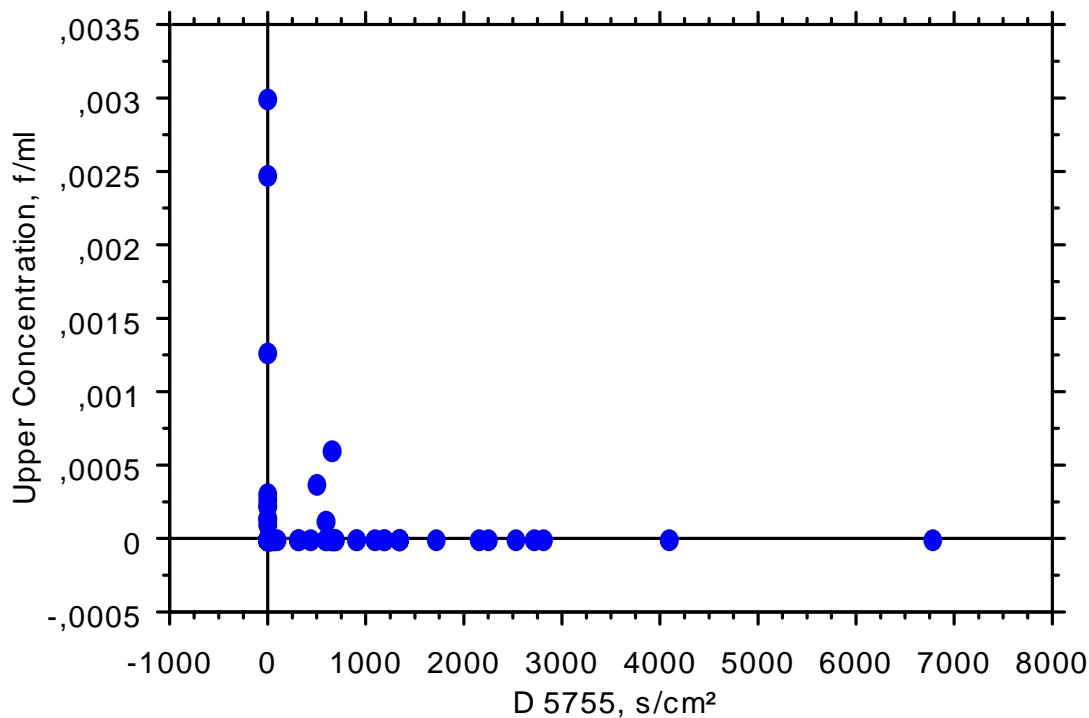

Figure 6. The correlation of airborne asbestos and asbestos in surface dust from 142 homes allegedly damaged during the 1995 Northridge earthquake.

The EPA has reported a similar graph (Figure 7) from studies they have conducted in Libby, MT. As in the Lee data, the vast majority of data points show either some reportable dust concentration with zero airborne asbestos or some airborne asbestos with zero asbestos in the surface dust. The EPA's data are shown in Figure 7.

<sup>20</sup> Lee, R. J., Van Orden, D. R., and Stewart, I. M. (2000). "Dust and Airborne Concentrations - Is There a Correlation?", *Advances in Environmental Measurement Methods for Asbestos*, ASTM STP 1342, M. Beard and H. Rook, Eds., American Society for Testing and Materials, p. 313 - 322.

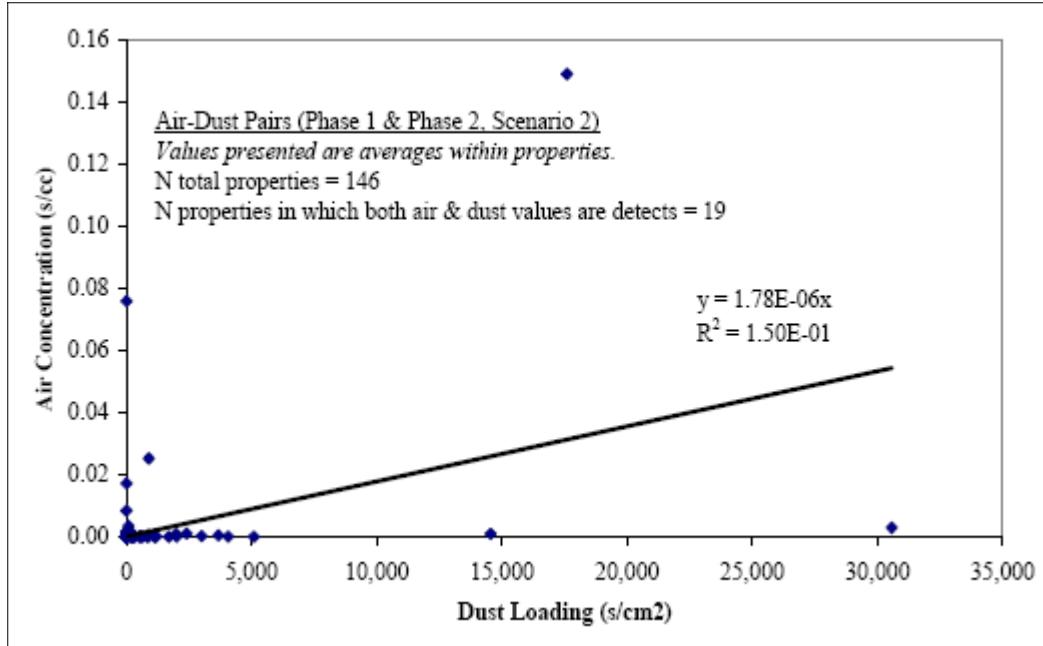

Figure 7. The correlation of airborne asbestos and asbestos in surface dust reported by the EPA from homes in Libby, MT. The vast majority of samples reported some dust loading, but no airborne concentration.

These data show there is no correlation between the amount of asbestos in surface dusts and the amount that is airborne. Because there is no correlation, there cannot be any relationship between the asbestos in surface dust and the amount that can be breathed by a building occupant or worker. These data support the statement from the ASTM D5755 method which states: "no relationship has been established between asbestos-containing dust as measured by this method and potential human exposure to airborne asbestos".

## 5.2 Determination of Dust Morphologies

The use of the method to suggest there are "free respirable size asbestos fibers & bundles" in the surface dust, as suggested by Dr. Longo and Mr. Ewing, is not an accepted practice. Because of the liberation of fibers from particles during the sample preparation, the analyst cannot determine whether the free fibers observed in the transmission electron microscope occurred on the surface in that manner or were liberated from larger particles during the sample preparation procedure.

RJ Lee Group tested a vermiculite-containing fireproofing material<sup>21</sup> to determine if free, respirable fibers became airborne as a result of hand crumbling the materials. Approximately 10gm samples of fireproofing were hand-pulverized over a 5-10 minute period until a majority of the pulverized material was smaller than 5mm. Air samplers were set up about 6 inches

<sup>21</sup> RJ Lee Group, Inc. (1992). Crumbling Experiment.

below and 6-12 inches laterally displaced from the point of crumbling. In addition, one sampler was located about 42 inches below with a 12 inch lateral displacement. Two samplers were placed in the debris stream directly below the point of crumbling. This arrangement permitted monitoring the air concentration during (5-10 minutes), after (20 minutes), and overall during the experiments. Over 40 experiments were conducted - no free asbestos fibers were observed on any air filter. Experiments conducted by Chatfield<sup>22</sup> on six asbestos-containing materials (including a fireproofing material with chrysotile, vermiculite and gypsum) support this finding.

## Expert Report

### *Limitations of Dust Sampling Methodology*

#### Qualifications

Dr. Richard J. Lee obtained a Bachelor of Science degree in physics from the University of North Dakota in 1966 and a Ph.D. in theoretical solid state physics from Colorado State University in 1970. He then went to Purdue University as an Assistant Professor in physics where he taught courses on the principles of optical microscopy. He received tenure at Purdue in less than two years.

In 1973, Dr. Lee went to work for United States Steel (US Steel), first as a research scientist and thereafter, as director of their physics and electron microscopy department in the Technical Center. He remained at the US Steel Research Center until 1985. While at US Steel, he analyzed a wide range of materials and was employed by NASA to analyze moon rocks brought back by the Apollo missions.

During his tenure at US Steel Research, Dr. Lee was responsible for developing the first techniques for quantitatively identifying amphibole asbestos fibers and cleavage fragments by a combination of transmission electron microscopy and energy dispersive X-ray analysis. He participated in the original ASTM committee that developed and evaluated the first TEM methods for preparing samples of air, bulk and water for the determination of asbestos content. Dr. Lee was the first scientist to develop methods for distinguishing asbestos amphiboles from cleavage fragments using transmission and scanning electron microscopy.

Since 1985, Dr. Lee has been President of a company now known as RJ Lee Group, Inc., ("RJ Lee Group") which has its principal office in Monroeville, Pennsylvania, and laboratories in San Leandro, California; and Manassas, Virginia. RJ Lee Group provides research, analytical and consulting services relating to materials characterization. Materials characterization of bulk building materials, also referred to as "constituent analysis", involves analyzing a sample of material using various techniques to identify and quantify the components of that material.

Dr. Lee has a long history of scientific consulting and service for government agencies, including the United States Environmental Protection Agency (EPA). RJ Lee Group's laboratory serves as a quality assurance and referee laboratory on a number of EPA programs. RJ Lee Group's laboratory performed the analyses for the EPA's major study on airborne levels of asbestos in public buildings. Dr. Lee has participated in the development by the EPA of analytical methods and procedures for asbestos analyses. The

EPA requested that he personally participate in several projects, including the drafting of the portions of the Agency's AHERA regulations governing air sample analysis after abatement. Dr. Lee was an invited member of the Health Effects Institute - Asbestos Research literature review panel, sponsored by the EPA. RJ Lee Group also has performed analyses for the United States Navy, the United States Army and the United States General Services Administration. Dr. Lee developed a program to determine the cause of failure in components of the guidance system in the Trident missile for the Department of the Navy.

RJ Lee Group's laboratory has also performed microscopic analyses for the State of California Air Resources Board when that agency performed testing of the air in major cities in the State of California to determine the presence of asbestos.

Dr. Lee is now engaged in and specializes in materials characterization, which is the science that uses a variety of analytical techniques to determine the identity and amount of each component of a material. He has performed materials characterization analyses on many samples of vermiculite produced from different sources for over 15 years. He is familiar with all methods of microscopy that are commonly used in characterizing asbestos or identifying and quantifying asbestos, including optical microscopy, scanning electron microscopy and transmission electron microscopy. He is also familiar with all known methodologies, from air sampling to dust sampling, with respect to asbestos. Dr. Lee is a member of the ASTM committee that has developed the dust sampling methods now in question. He has worked extensively with, and is an expert in, analytical techniques including light and electron microscopy, materials characterization, asbestos air, bulk, and dust samples, and methods of evaluation. He has also served as an expert witness in litigation involving asbestos in buildings and has testified in state and federal courts.

Dr. Lee is familiar with airborne levels of asbestos fibers both in buildings and in outdoor air, the sources of asbestos in the outside or ambient air, scientific knowledge and techniques regarding the measurement of levels of asbestos in the air, the development and use of the technology to measure both airborne levels of fibers and levels in materials samples, and the standards and methods used for air sampling. He has been involved in analyzing and producing bodies of air sampling data for EPA and other governmental and private entities including analysis of samples taken in an ongoing nationwide study of airborne levels in buildings and his analysis of air samples taken in an EPA-sponsored study in Texas.

He is also familiar with the history of standards governing asbestos including the current standards, regulatory positions and philosophies,

different types of asbestos fibers, asbestos fiber levels as reported in the literature, as well as his own work concerning buildings with asbestos-containing materials.

Dr. Lee's fee for consulting, depositions, and trial appearances is \$350 per hour.

## Summary of Opinions

Dust sampling and analyses, as applied to dust and debris from in-place building materials, are not reproducible.

The reported asbestos concentrations for dust samples do not accurately represent the concentration of asbestos in surface dust and debris. The use of the "indirect" sample preparation method for analyzing surface dust modifies the collected material by shaking and sonicating the sample in an acidic solution. Data derived from "indirect" preparation have very large variability; the number of asbestos structures is exaggerated due to the sample preparation procedure.

Because of the "indirect" sample preparation procedures used for dust analyses, the dust methods are particularly unsuited for analyzing debris from a cementitious fireproofing or acoustical plaster product. The "indirect" method dissolves the matrix materials binding the asbestos fibers together, generating or liberating individual, free asbestos fibers that were not present as such in the surface dust.

Dust sampling and analyses are not recognized within the scientific or regulatory communities as a means of assessing or predicting inhalation exposure and have not been incorporated into any regulatory standards for such use.

Dust sampling and analyses provide no information on past or future concentrations of respirable asbestos fibers that are or may be in the air.

## Physical Characteristics, Composition and Properties of Fireproofing Acoustical Plaster Materials

Fireproofing materials are applied to the surface of decks, beams and other structural members of buildings. Sprayed on fireproofing containing asbestos was applied by either wet or dry methods beginning in the late 1950's through the early 1970's. In the dry method, the materials are blown through a tube and mixed with water at the point of application. In the wet process, the materials are mixed with water, then pumped through a tube and sprayed on structural steel. In both cases, the action of a water-

activated binder causes them to stick to the surface and when dried or set, form a resilient cohesive coating.

The primary requirement of fireproofing materials applied to steel structures is that they both prevent the spread of fire and protect the steel structure against deformation, at least for sufficient time to permit safe evacuation of building occupants. Thus, they must be fire resistant: they must provide a mechanism for the safe dissipation of heat away from the steel members which they protect and they must retain their integrity, both long term over the life of the building and short term when subjected to a fire episode.

Acoustical plaster materials were applied to ceilings and walls of buildings. The materials were sprayed-on or troweled on depending on the particular use. As applied, water would cause a chemical bonding to take place in the product encapsulating any fibers in the product. These materials (with asbestos) were in use from the late 1950's through the early 1970's.

The general composition of the acoustical plaster products was a binder (cement or plaster of paris) combined with a light-weight aggregate (vermiculite or perlite), asbestos (chrysotile), and sometimes some clay (montmorillonite or bentonite). Other additives were used to improve setting, increase the whiteness of the product, or reduce bacterial growth in the product.

The principal function of acoustical plasters is to reduce ambient levels of sound in a room by partial adsorption of the sound and by selective reflection of the sound. The products, while providing an architecturally acceptable surface finish, adhere to building materials such as ceiling decking, metal duct work, and other wallboard or plaster finishes.

Some of the binder materials also undergo a chemical reaction with water, precipitating onto and encapsulating the remaining particles; these reacted materials are known as cementitious.

The American Society for Testing and Materials (ASTM), an organization which defines terms, standards and testing methods for materials, defines a cementitious material as "A material that, when mixed with water, with or without aggregate, provides the plasticity and the cohesive and adhesive properties necessary for placement and the formation of a rigid mass". Implicit in this definition is the ability of the material to adhere to the structure to which it is applied not only during application but also after setting up in place. The constituents of these WR Grace fireproofing and acoustical products are such that the material meets ASTM's definition of cementitious.

## Asbestos-Containing Fireproofing and Acoustical Plaster Materials do not Spontaneously Degrade or Shed Individual, Free Fibers

The constituents of the cementitious fireproofing materials and acoustical plasters at issue are stable and do not spontaneously degrade or shed individual fibers even when physically or chemically attacked.

Constituents which were used in the WR Grace products, in addition to minor quantities of asbestos, were plaster, gypsum and vermiculite. Thus, the materials used in the formulation of the products at issue are, after setting, chemically inert with respect to normal building conditions. The bonding action between the cementitious matrix and its fiber reinforcement results in products which are dimensionally stable and possess excellent cohesion by virtue of the reinforcing action of the asbestos fibers in their formulations. They do not degrade or release components spontaneously. They do not spontaneously delaminate or lose adherence if they are correctly applied and if the building is properly maintained.

When applied and maintained appropriately, these products will withstand degradation due to impact, bending, compression and air erosion. The materials of interest in this case are inert, non-reactive materials. They have been consolidated into a system which in and of itself will not degrade or deteriorate. Unless improperly applied, or subjected to adverse environmental conditions, these materials will maintain their integrity.

The components of these materials are found in nature giving rise to their intrinsic stability. The asbestos is encapsulated or otherwise tightly enmeshed by the primary constituents and itself becomes an interlocking member of the system. Even when mechanically disturbed or intruded upon the system will fracture in such a manner as to release debris particles, not individual respirable asbestos fibers.

These materials have been subjected to a variety of air erosion tests<sup>1,2,3</sup> which demonstrated, within the state-of-the-art, that they did not release individual asbestos fibers. In addition, RJ Lee Group has subjected the

fireproofing material to extensive pulverization tests<sup>4</sup> demonstrating that no significant airborne fiber levels were generated by the action.

## Dust Sampling and Analysis

Dust sampling and analysis is a methodology by which dust is collected from a surface and the content of asbestos evaluated. The dust may be collected by a technique known as a microvacuum or a microvac, in which a partial vacuum is created at a membrane filter surface and dust particles pulled from a surface are deposited either on the filter surface or in the cassette holder. A variety of other methodologies are also employed including application of a sticky surface (adhesive lift) sample to the dust to collect particles, or wiping a damp cloth or filter (wipe sample) over the surface. The analysis of these samples for asbestos content can be performed by optical or electron microscopy.

Sample preparation of surface dust samples is accomplished utilizing an "indirect" methodology. In the indirect analysis particles are removed from collection media, suspended in acid water, and subjected to mechanical agitation (currently employing ultrasonic treatment). The sonication time varies from three to fifteen minutes. A portion of the suspended material is then deposited onto a membrane filter for microscopic analysis.

The development of the dust procedures began in the 1980's as an outgrowth of AHERA building inspections. During these inspections, dust was observed on the top of ceiling tiles, on top of bookshelves, or other areas which were not routinely cleaned. It was theorized that this dust may contain asbestos, but there were no published methods for the collection and analysis of this matrix. RJ Lee Group participated in the formulation and development of these dust sampling analytical methods.

## EPA Dust Protocol

In 1989, the U.S. Environmental Protection Agency (EPA) hosted a meeting in Cincinnati to discuss dust sampling and analysis. The outgrowth of this meeting was a draft EPA protocol<sup>5</sup> which was designed to improve "the degree of precision for this analysis". However, as noted by the method, the accuracy of the method was in question as "no single type of microscope can accurately cover the entire range of fiber sizes without relatively over- or under-estimating asbestos concentrations".

<sup>4</sup> RJ Lee Group, Inc. (1995). Videotape: The Measurement of Fiber Release During Pulverization of Friable Fireproofing, September 29, 1995.

<sup>5</sup> P. J. Clark and K. Brackett (1990). "Draft Test Method for Sampling and Analysis of Dust for Asbestos Structures by Transmission Electron Microscopy", U.S. Environmental Protection Agency, Cincinnati, OH.

Though developed as a standard procedure, the dust procedure was never meant to be used alone. As noted in the draft EPA procedure: "This technique will augment visual inspection and air monitoring". Thus, it provides supplementary information to the primary building survey techniques - visual inspection, air monitoring and bulk sample analyses. The method was also designed to collect all dust on a surface, even extremely adherent dust where "a small spatula may have to be used to dislodge the particulates before microvacuuming the surface".

More significantly, the EPA acknowledged that the sample preparation procedure for the microvacuum method increases the number of counted asbestos fibers: "As this method involves the use of sonication to disperse the fibers in the dust sample prior to dilution and filtration, it will increase the number of small fibers counted in relation to what may have actually been found on the surface." The manner in which "indirect" preparation alters the number and character of asbestos structures in the dust is discussed in detail below.

### **ASTM Dust Procedures**

The draft EPA procedure was submitted to the ASTM asbestos committee (currently D22.07) for consideration and development into a standardized method. The development by ASTM of standardized methods is the result of a consensus procedure. The methods do not require a unanimous vote to be approved, only a super-majority affirmative vote of the committee members. Disagreements and negative votes on balloted items are discussed at biannual meetings. Negative ballots must be considered, but can be deemed "non-persuasive" by a super-majority of the attending committee members. Thus, a method having been approved does not imply unanimous agreement - there may be technical issues unresolved but acceptable to a majority of committee members.

Balloting on the surface dust method began in early 1990 with a final consensus version not completed until 1995. At that time, the microvacuum method, ASTM D-5755-95<sup>6</sup>, was issued. That method involves collection of samples by a microvacuum, indirect sample preparation, and results reported as the number of asbestos structures per square centimeter of sampled surface. During its five year development, significant changes were made to the method, both qualitative and quantitative, following vigorous committee discussions. In addition, a parallel method (ASTM D-5756-95)

---

<sup>6</sup> The published ASTM dust methods can be found in volume 11.03 of the *Annual Book of ASTM Standards*, American Society for Testing and Materials, Conshohocken, PA.

that measures the mass of asbestos in surface dust was started in 1993 and moved through balloting in tandem with the structure count method.

The ASTM methods include directives and guidance that delineate the usefulness and limitations of the method. The method is limited to the "general testing of non-airborne dust samples for asbestos". As noted, the "collection efficiency of this technique [microvacuum] is unknown and will vary among substrates". Like the draft EPA protocol, the ASTM method also acknowledges that the indirect sample preparation procedure "may alter the physical form of the mineral fibers".

One of the fundamental changes made to the draft EPA method when converting it into an ASTM method was to modify the definition of "dust". The draft EPA defined dust particles as 20  $\mu\text{m}$  and smaller. In the ASTM methods, however, a much larger sized particle, 1 mm and smaller, was embodied in the definition. Because the sample collection nozzle is passed over a surface on which a range of particle sizes may occur, any particle that can fit into the nozzle will be collected, not just particles that may be respirable in size. Therefore, the definition of dust was increased to the larger size.

Considerable variation has taken place and continues to take place in the application of the microvacuum sampling and analysis methodology for settled dust. Thus, no scientifically viable conclusion may be drawn from dust samples collected in this manner.

Furthermore, despite the efforts of ASTM to develop standard methods, sample collection is far from standardized. For example, some practitioners apply pressure on the surface sampled in order to dislodge dust from it. Such pressure is not called for in the ASTM standards because it is difficult if not impossible to accurately apply this pressure. Because the pressure will vary and have unpredictable results on the amount of material collected, data from one area cannot be reliably compared with data from other locations.

The ASTM methods specifically state that "no relationship has been established between asbestos-containing dust as measured by [these methods] and potential human exposure to airborne asbestos".

Following completion of the two microvacuum sampling methods, a third method was developed by the ASTM committee. Currently designated as D 6480-99, this method uses a wet wipe (such as a clean room wipe) to collect the surface dust. Unlike the microvacuum technique which attempts to limit the collected particles to those smaller than 1 mm, the wipe procedure collects all particles deposited within a designated sampling area. The first

draft of the method was balloted in 1996; final balloting and passage of the method occurred in 1999.

### Dust methods do not measure the dust as it occurs on the surface

The sample preparation methods used in measuring the asbestos content of dust collected by the ASTM methods results in distortion of both the sizes and number of asbestos structures in the sample. In particular, ultrasonic treatment, especially in combination with the use of acidified water, so disrupts the asbestos particles present in asbestos-containing dusts as to nullify any attempt at estimating their number concentration.

The ability of ultrasonic energy to disrupt asbestos particles and split them into finer particles has not only been known for many years, but was in fact a basis for mineral beneficiation of chrysotile ores in the early 1960's.<sup>7</sup> Sample preparation procedures for transmission electron microscopic examination in the late 1960s and early 1970s was based on the use of ultrasonics. Spurny<sup>8</sup> reported on the effect of ultrasonic treatment of asbestos fibers, reporting on changes to the size and aspect ratio of fibers. In studies of asbestos in water, Chatfield<sup>9</sup> quantified the breakup of asbestos by ultrasonics and showed how it increased with time and input power. Chesson<sup>10</sup> conducted a statistical study of comparisons of direct and indirect preparation of air samples and showed that in all cases the number of fibers observed in indirect preparations were higher than in direct preparations. Burdett<sup>11</sup> compared direct and indirect sample preparation and concluded that the indirect method modified the fiber count by breaking up agglomerates and that the direct preparation procedure was useful for exposure assessment.

Sahle<sup>12</sup> and Kauffer<sup>13</sup> similarly showed that indirect sample preparation induces very high apparent fiber concentrations due to the action of

ultrasonic treatment, which results in the breakdown of fibers in both length and diameter.

Our own work has shown that ultrasonic treatment results in the breakup of fireproofing debris particles, as well as the break-up of asbestos fibers of the size present in asbestos-containing fireproofing. We have demonstrated<sup>14</sup> that this breakup occurs early in the ultrasonic process. Through the use of ultra slow motion videography, we have demonstrated that this breakup is often explosive and instantaneous when the ultrasonic power is applied, with massive disruption of debris particles from an asbestos-containing fireproofing or of Grade 7M asbestos particles occurring within three seconds of application of the ultrasonic power. We have performed an inter-laboratory comparison of the effect of indirect preparation on single particles of fireproofing and asbestos bundles.<sup>15</sup> The results demonstrate that a single non-respirable particle of fireproofing products, when subjected to the sample preparation procedures of the indirect microvac protocol, produces the equivalent of hundreds of millions of fibers in the final result.

Lee<sup>16</sup> points out that the dilutions used by various laboratories also differ significantly and contribute to large variability between laboratories. Variations in dilution factors are thus likely to account for more variability than does location of the sample.

Because the matrices of the cementitious fireproofing and plaster materials are soluble in acid, the dust method's use of acidified aqueous suspension results in the dissolution of these matrices and consequential release of asbestos fiber bundles that would otherwise remain encapsulated in the fireproofing. Once released, these fiber bundles are more susceptible to ultrasonic disruption than they would be when held in their cementitious matrix. Consequently, the combined use of ultrasonic treatment and acidified aqueous suspensions synergistically leads to enhanced fiber breakup and thus to artificially increased concentrations of fibers in the dust. As a result, the fiber bundles observable to the naked eye become subdivided into numerous smaller fibers.

Every author reporting on comparison of direct and indirect preparation recognized that the indirect preparation method modifies the sample and increases the fiber count.<sup>8,9,10,11,12,13,14,15,16</sup> Those that have conducted detailed experiments conclude that the increase results from the break-up or dissolution of particles containing asbestos and from modification of the fiber size distribution, i.e., breakage of longer fibers into shorter fibers and bundles of fibers into individual fibers.<sup>15,16,17</sup> As a result the numerical concentration of asbestos reported by the ASTM dust procedures has no relationship to the asbestos structures as they occur in the dust on the surface.

Dement, a former Director of the National Institute for Environmental Health Sciences, succinctly summarizes the issue with indirect preparation when he states<sup>18</sup>: "The use of indirect sample transfer for transmission electron microscopy (TEM) of asbestos has been shown to break up the airborne fibers into smaller units. Depending upon the treatment, the observed concentration of fibers and their size distribution change drastically. There is no biological justification for such a violent treatment, and the measured entity is not a biologically justifiable measured quantity. Therefore, the use of indirect sample transfer method for asbestos sampling should be discouraged and the more gentle direct transfer method should be used."

In summary, the indirect ASTM dust procedures modify the sample making it impossible to evaluate whether asbestos in surface dust is individual, free and respirable fibers or particles of debris that have been broken up in the process.

### Surface dust in typical buildings with ACM does not readily become airborne

Surface dust does not readily become airborne. The particle size, cohesion and moisture content affect the ability of surface dust to be resuspended. High air velocities, in excess of 100 mph, were necessary to liberate asbestos fibers from a surface. Guillaman<sup>19</sup> found increased levels of fibrous particulate during periods of high activity in schools, but no increase in

asbestos concentrations. Guth<sup>20</sup> estimated the contribution of surface dust to airborne concentrations at less than 1% of the available particles.

A study by the Missouri Department of Health<sup>21</sup>, cited by OSHA in their 1994 rulemaking, found that a variety of custodial activities including dry sweeping of asbestos-containing dust and debris produced airborne concentrations well below the OSHA limit. Our own analysis of air samples related to clean-up of asbestos-containing dust and debris following an earthquake found virtually all samples to be below the PEL<sup>22</sup>.

Millette and Heffernan<sup>23</sup> reported concentrations well below the PEL when dry sweeping asbestos dust produced during a simulated maintenance activity.

### Dust sampling is not recognized as a means of exposure assessment

Dust sampling and analysis, in contrast to air sampling, is not recognized within the scientific, regulatory or industrial hygiene communities as a means of assessing or predicting exposures. It has not been incorporated into any regulatory standard, nor is there any literature correlating the results of microvacuum dust sampling to airborne concentrations of asbestos.

Mr. Michael Beard, formerly with EPA's Quality Assurance Branch in Raleigh, NC, was a frequent presenter at technical meetings, symposia and courses in the early 1990's. In courses on settled dust analysis, sponsored by the Georgia Institute of Technology, by the Environmental Information Association and by ASTM, Mr. Beard repeatedly stressed that EPA has neither an official method for the analysis of asbestos in settled dust nor an official policy for its use.

## There is no correlation between dust sample results and airborne levels of asbestos

Results of microvac dust sampling bear no correlation or relationship to either past or potential airborne levels<sup>24</sup> in buildings. In fact, the ASTM dust method itself recognizes this limitation. The ASTM D5755 method states (section 5.1.2): "At present, no relationship has been established between asbestos-containing dust as measured by this test method and potential human exposure to airborne asbestos."

An extensive data set of air and dust samples collected in residential properties was evaluated to determine whether any correlation exists between airborne concentrations of asbestos and asbestos concentrations measured in settled dust. These samples were collected in buildings that were allegedly damaged during an earthquake in southern California. Interior airborne asbestos concentrations were higher than outdoor concentrations; indoor airborne levels did not correlate with asbestos concentrations in the dust as measured by the indirect ASTM TEM methods. The presence of asbestos in the surface dust was shown to be independent of the presence of asbestos in bulk samples collected from the residences. The presence of airborne asbestos was also shown to be independent of the presence of asbestos in surface dust. Thus, observing asbestos in a dust sample does not imply that asbestos will be found in an air sample nor does it imply that asbestos will be found at some predictable concentration.

Chatfield<sup>25</sup> has produced supporting documentation that shows the airborne particles from a controlled abrading of ACM are not correlated with dust that fell to the surface. He showed that the individual chrysotile fibers observed in the surface dust, when indirectly prepared in accordance with ASTM D5755, "could not have been present in the original dust and debris which settled" during the tests and that the "numbers, sizes and characteristics of the chrysotile structures ... were therefore not representative of the particles as they existed on the original surface".

Fowler and Chatfield<sup>26</sup> conclude that dust sampling has little value for predicting potential airborne concentrations especially if indirect

preparation is used. Sansone<sup>27</sup> warns that interpretation of dust sample analysis and resuspension data is subject to many variables.

The EPA also notes that asbestos in dust and airborne asbestos are not related:<sup>28</sup> "At present no firm conclusions can be drawn regarding potential exposure hazards from asbestos contaminated surface dust and no limits have been set to define a level requiring abatement or cleaning of an area."
